

P

Pacific Islands, Archaeology of

The Pacific Islands, also known as Oceania, have been subdivided traditionally by anthropologists into three main geographic regions: Melanesia, Micronesia, and Polynesia. Following Green (1991), prehistorians now stress the division between *Near Oceania* in the west (including the Bismarck Archipelago and the Solomon Islands), and *Remote Oceania* (which includes all of island Melanesia southeast of the Solomons, along with Polynesia and Micronesia). This latter distinction recognizes the Pleistocene settlement of Near Oceania, whereas the widely dispersed islands of Remote Oceania were discovered and settled only within the past 4,000 years. Archaeological research in Oceania has a long history, but modern efforts emphasizing stratigraphic excavations did not begin until after World War II (Kirch 2000), and have revealed the main chronological sequence for human settlement. This sequence is summarized here, followed by reviews of the development of complex societies in Oceania, and of the human impact on island environments.

1. Early Human Settlement of Near Oceania

The oldest known occupation sites are radiocarbon dated to ca. 36,000 years ago (the late Pleistocene), on the large island of New Guinea and in the adjacent Bismarck Archipelago (Allen 1996). At several times during the Pleistocene, New Guinea was joined to Australia as a single land mass (known as Sahul), and human entry into and expansion throughout this vast Australasian region occurred rapidly. Late Pleistocene sites in the Admiralty Islands, New Ireland, and Buka (Solomons), all would have required open ocean transport, suggesting the presence of some form of watercraft (possibly rafts, bark boats, or dugouts) (Irwin 1992).

Early human colonists in Near Oceania were hunters and gatherers, who exploited tropical rainforests as well as inshore marine resources (see *Hunter-Gatherer Societies, Archaeology of*). Long-distance communication and exchange is indicated by the movement of obsidian between islands. By the early Holocene period (after 8000 BC), there is archaeological evidence for domestication of tree, root, and tuber crops (such as the *Canarium* almond and various aroids) within Near Oceania. Archaeological evidence for the cultivation of swamplands at Kuk in

the Highlands of New Guinea commences as early as 7000 BC (Golson 1988). These archaeological indications confirm the long-held ethnobotanical hypothesis that Near Oceania was one of several independent centers for the origins of tropical horticulture (see *Food Production, Origins of*).

2. Austronesian Expansion and Lapita

During the early Holocene, the southeastern Solomon Islands marked the limit of human expansion. Beginning around 2000 BC, a major expansion or diaspora of people speaking languages belonging to the Austronesian language family commenced (Blust 1995). Their immediate homeland has generally been regarded as comprising the island of Taiwan (and perhaps adjacent areas of mainland China). The ability of early Austronesians to disperse rapidly has been attributed to their invention of the outrigger sailing canoe (Pawley and Ross 1993). The Austronesians were horticulturalists who transported root, tuber, and tree crops via their canoes, along with breeding stocks of domestic pigs, dogs, and chickens.

The Austronesian diaspora rapidly encompassed the major archipelagoes of island Southeast Asia; one branch of Austronesian-speakers expanded along the north coast of New Guinea into the Bismarck Archipelago. This branch is known to linguists as Oceanic, and the Oceanic languages (numbering about 450 modern languages) include most of those spoken throughout the Pacific. The great exception is New Guinea, where roughly 750 non-Austronesian languages are spoken.

Archaeological evidence for the initial Austronesian dispersal into the Pacific comes from both western Micronesia (the Marianas and Palau archipelagoes), and from the Bismarck Archipelago. In western Micronesia, early sites contain red-slipped pottery, some of which is decorated with lime-filled, impressed designs (Rainbird 1994). These sites, along with radiocarbon-dated sediment cores exhibiting signals of human presence (e.g., high influxes of microscopic charcoal resulting from anthropogenic burning) suggest that humans settled the Marianas and Palau no later than 1500 BC, and possibly as early as 2000 BC.

In the Bismarck Archipelago, the initial Austronesian incursion has been correlated with the appearance of a distinctive suite of sites, also containing pottery with lime-infilled decorations, but with motifs

made largely by a technique of dentate-stamping. These sites and the associated artifacts (such as *Tridacna*-shell adzes and *Trochus*-shell fishhooks, as well as ornaments) represent the earliest known phase of the Lapita cultural complex, dating to ca. 1500–1300 BC (Gosden et al., 1989, Spriggs 1997). Early Lapita sites were frequently hamlets or villages consisting of houses elevated on posts or stilts, situated over tidal reef flats or along shorelines. Excavated plant and animal remains indicated a mixed economy with horticulture and marine exploitation. Substantial quantities of obsidian, chert, pottery, shell artifacts, and other materials were exchanged between communities (Kirch 1997).

Correlations among archaeological assemblages, language groups, and human biological populations are often complex, and need not be isomorphic. However, a strong consensus is emerging among scholars in several disciplines that the initial phase of the Lapita cultural complex can be correlated with the Proto Oceanic interstage of the Austronesian language family. Moreover, genetic evidence (such as mtDNA and hemoglobin markers) supports the view that the Lapita phenomenon reflects a substantial population intrusion into the Bismarck Archipelago, deriving out of island Southeast Asia (Hill and Serjeantson 1989). At the same time, the Proto Oceanic speakers undoubtedly had considerable interaction (cultural, linguistic, and genetic) with the indigenous non-Austronesian speaking populations who already occupied the Bismarck region in the mid-Holocene. Thus the Lapita cultural complex is seen as an outcome of cultural processes of intrusion, integration, and innovation.

3. Human Colonization of Remote Oceania

Beginning ca. 1300 BC, the Lapita pottery makers expanded rapidly beyond the Solomons and into the southwestern archipelagoes of Remote Oceania: Vanuatu, the Loyalty Islands, New Caledonia, Fiji, Tonga, and Samoa. Numerous radiocarbon-dated archaeological sites document that Lapita sites in all of these archipelagoes are no later than 900 BC.

We have already noted that the westernmost islands of Micronesia were colonized directly out of island Southeast Asia by Austronesian speakers ca. 2000–1500 BC. Around 2,000 years ago, Oceanic speakers who made plainware pottery (a late form of Lapita) and who used shell adzes, fishhooks, and other implements, founded settlements on several volcanic islands of central Micronesia (Chuuk, Pohnpei, and Kosrae). The atolls of the Marshall Islands were also colonized at this time.

The final stage in the human settlement of the Pacific Islands began after 500 BC, with the Polynesian dispersals eastwards out of Tonga and Samoa. Ancestral Polynesian culture and Proto Polynesian lan-

guage themselves had developed in this Tonga–Samoa region between ca. 900–500 BC, directly out of the founding Lapita cultural complex (Kirch 2000, Kirch and Green, in press). While archaeologists debate the exact chronology and sequence of Polynesian dispersals, most agree that the central Eastern Polynesian archipelagoes (such as the Society Islands, Cook Islands, and Marquesas Islands) were settled first, no later than AD 300 and perhaps some centuries earlier (Rolett 1998). Remote Easter Island was discovered by AD 800–900 (Van Tilburg 1994), while the Hawaiian Islands were also well settled by this date. The twin large, temperate islands of New Zealand were colonized by Polynesians around AD 1200 (Anderson 1989, Davidson 1984). Critical to the success of this unprecedented diaspora was the double-hulled sailing canoe, capable of carrying 40–60 people on voyages lasting one month or longer (Irwin 1992). That the Polynesians reached South America and returned is suggested by preserved remains of the sweet potato (*Ipomoea batatas*), a South American domesticate, in several prehistoric Polynesian sites.

Because it was the last sector of Remote Oceania to be settled, and because its populations represent a single radiation or diaspora, Polynesia constitutes a monophyletic cultural and linguistic group. Thus, Polynesia has often been regarded as an ideal region for testing models of cultural differentiation from a common ancestor (e.g., Kirch 1984, Kirch and Green, in press).

4. Development of Complex Societies

When the eighteenth- to nineteenth-century European voyages of discovery inspired by the Enlightenment encountered Pacific island societies, they frequently encountered large, dense populations organized into complex, hierarchical sociopolitical formations. With populations often numbering into the tens or hundreds of thousands, such societies had two to three decision-making levels, and hereditary leaders who enjoyed elite privileges and status markers. Anthropologists classify such sociopolitical formations as chiefdoms, and indeed, the Polynesian chiefdoms are often considered the archetypal model (see *Chiefdoms, Archaeology of*).

The origins, development, and elaboration of Pacific island chiefdoms have been a major topic of archaeological research (e.g., Davidson 1984, Kirch 1984, Rainbird 1994, Sand 1995, Spriggs 1997). Based on linguistic and archaeological evidence, early Austronesian societies were characterized by some degree of internal ranking (especially between senior and junior branches of a descent line), but were probably heterarchical rather than hierarchical in structure. However, heterarchic competition (in such social arenas as marriage and exchange, as well as competition for land) between social groups provided the

basis for true hierarchy (and eventually, in the largest societies, class stratification) to emerge.

Archaeologists have identified several factors and processes that were significant in the rise of Oceanic chiefdom societies. Many of these were closely linked, and should not be considered unicausal variables. For example, population growth leading to large, high-density populations can be identified as a necessary, but probably not sufficient, cause underlying socio-political complexity (Kirch 2000, Sand 1995). The human populations of the volcanic islands typically reached densities of between 100–250 persons per square kilometer prior to European contact, resulting in intense competition for arable land and other resources. Such conditions encouraged centralized, hierarchic control, as well as providing incentives for militaristic aggression.

A second process linked to population growth and to increased hierarchy was intensification of production, including agricultural systems and other forms of production or resource extraction, as well as economic specialization (e.g., in pottery production and trade). On many islands, large-scale irrigation works or dryland field systems were developed during late prehistory. Although population increases may have initially spurred intensification, once in place such intensive production systems provided a means for surplus extraction by chiefs and other leaders, thus encouraging hierarchy. Often culturally marked as tribute, such surpluses were the economic foundation of an emergent elite, including not only hereditary chiefs, but priests, warriors, craft specialists, and others.

Ideology likewise played a key role in Pacific island societies, with the elite cadres of the larger and most complex societies actively employing ideological control as a means of legitimation. The origins of Oceanic ritual systems can be traced back to common Austronesian concepts of the sacredness of ancestors; these concepts later became elaborated as cults in which the highest chiefs were seen as directly descended from powerful gods, and hence essential to the continued well-being of the society at large. Archaeologically, the rise of elite-dominated ideological systems is particularly reflected in monumental architecture, of which the most impressive examples are the giant statue-bearing temples of Easter Island, and the site of Nan Madol on Pohnpei. Other forms of monumental architecture, however, are ubiquitous throughout Pacific islands chiefdoms. Even when monumental architecture is absent, material signs of ideological control can be quite striking, as in the multiple sacrificial interments associated with the burial of Roy Mata, a chief of Vanuatu (Garanger 1972).

Finally, competition, conflict, and warfare also characterized many of the complex societies of the Pacific, especially following the rise of large and dense populations (see also *Cultural Resource Management (CRM): Conservation of Cultural Heritage*). Arch-

aeologically, warfare is marked by a diversity of kinds of fortifications, such as the pallisaded *pa* volcanic cones and headlands of New Zealand, or the ring-ditch fortified villages of Fiji. Another, more gruesome signal of the levels that inter-societal aggression reached on some islands is cannibalism (or para-cannibalistic treatment of enemies, such as dismembering, roasting, and the nonfunerary discard of skeletal remains). Although some anthropologists have expressed skepticism regarding the accounts of cannibalism in the Pacific by European voyagers, there is now direct archaeological evidence for cannibalistic or para-cannibalistic practices in late prehistory on Easter Island, the Marquesas, New Zealand, Mangaia, and Fiji.

5. Human Impacts to Island Ecosystems

The islands of Remote Oceania, due to isolation and related factors, provide model conditions for studying the effects of human colonization and land use on pristine ecosystems. Interdisciplinary research among archaeologists and natural scientists (see also *Environmental Archaeology*) over the past three decades has amplified our understanding of such human–ecosystem interactions (Kirch and Hunt 1997).

Because of the substantial open-ocean distances isolating them from continents as well as other islands, and the difficulty of dispersal to islands, prior to human arrival oceanic ecosystems were typically characterized by: high species-level endemism, but lower diversity in higher-level (generic and family) taxa; lowered competition; survival of archaic forms; and vulnerability to disturbance from outside agents. Larger vertebrates such as marsupials (wombats, cuscus) and rats, snakes, frogs, and most lizards were restricted primarily to Near Oceania, with only a handful of species declining in numbers eastwards to Fiji and Samoa. (The reef and marine resources of Pacific islands also display a west-to-east decline in species diversity.) Throughout most of Remote Oceania, prehuman vertebrate faunas were dominated by birds (including many flightless forms which had evolved *in situ* from flighted ancestors). Prior to human arrival, these bird populations lacked large vertebrate predators, and presumably also a typical predator avoidance strategy. They must have been extremely easy prey for the first humans to step foot on these islands.

When humans first arrived in Remote Oceania, they typically found the islands to be forested, and inhabited by a range of largely endemic species, dominated by birds, along with invertebrates such as land snails and insects. Oceanic peoples possessed a successful colonization strategy that allowed them to exist on isolated islands, by: (a) transporting in their sailing canoes stocks of horticultural crop plants, along with domestic pigs, dogs, and chickens (rats came along,

presumably as 'stowaways'); (b) clearing areas of rainforest for garden land; and (c) intensively exploiting the abundant natural avifaunal and marine resources.

This colonization strategy had several consequences for island ecosystems, all of which are increasingly well documented through both archaeological and paleoenvironmental indicators. Forest clearance on many islands is signaled in changing pollen spectra from sediment cores, with tree taxa rapidly giving away to ferns and grasses; also characteristic are sharp increases in microscopic charcoal influxes, indicating human-induced burning, in most cases probably associated with shifting cultivation. On some islands, forest clearance led to increased erosion rates, along with alluviation of valley bottoms or along coastal plains. The exploitation of natural resources is particularly evident in the zooarchaeological assemblages from early settlement sites, which are characterized by high numbers of land and seabirds, many of them representing now extinct or extirpated species (Steadman 1995). A dramatic case of avifaunal extinctions on Pacific islands is that of the moa, a group of 13 species of large, flightless birds which became totally extinct in New Zealand during the brief period of Polynesian occupation (Anderson 1989).

Cumulative effects of human actions on islands led to irreversible changes, such as dramatic declines in biodiversity, and the conversion of natural rainforests to intensively managed, anthropogenic landscapes. The consequences for human populations themselves were undoubtedly mixed. The replacement of natural ecosystems with intensive food production systems enabled the growth of large and dense human populations. At the same time, reduction or depletion of natural resources, coupled with the necessity for intensive land use, encouraged highly complex sociopolitical systems which at times competed fiercely for control of land and the means of production.

Pain, Health Psychology of

1. Basic Terms

Pain is an adaptive phenomenon that signals impending danger to the body. Pain can, however, also be maladaptive, for example in states of chronic pain, and thus can itself become a significant disorder. Epidemiological studies show that 80 percent of the population experience recurrent pain, with more than 10 percent of the population being permanently disabled by it. Although pain has for a long time been

viewed a purely sensory phenomenon or an epiphenomenon of a medical disorder, this view changed during the last 40 years of the twentieth century. It has been recognized that pain is a psychobiological experience, with emotional aspects being as important as sensory pain characteristics. Thus nociception, the physiological process of a noxious signal being transmitted from the periphery to the brain, has been differentiated from the experience of pain, which encompasses all aspects including psychological, social and cultural factors. The international Association for the Study of Pain (IASP) definition takes this shift from a biomedical to a biobehavioral or psychobiological perspective into account by characterizing pain as an 'unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage' (Merskey 1986). This definition was prompted by the fact that pain may often be experienced in the absence of identifiable objective pathology. A major change in the traditional view of pain was the gate control theory of pain proposed in Melzack and Wall (1965). More important than its physiological aspects, which have not all been confirmed, was the conceptual model behind it. The gate control theory stated not only that pain could be modulated by both afferent and efferent factors at the level of the spinal cord, but also emphasized that pain has sensory-discriminative, motivational-emotional, and cognitive-evaluative components as well, and thus it assigns an important role to psychological factors. A core feature of this model is the integration of peripheral stimuli with psychological variables such as mood, attention, or cultural experience in the perception of pain. Thus, the gate control theory has been instrumental in abolishing the dichotomy of psychogenic versus somatogenic pain—psychological and physiological factors always interact in the production of the experience of pain and are not mutually exclusive causes of pain.

2. Classification of Pain

The common distinction between acute and chronic pain—referring to pain of at least three to six months duration and/or pain that exceeds the normal time for healing in the case of an acute injury—is useful, because chronic pain is often maladaptive and needs special attention. Whereas acute pain such as pain related to medical procedures or childbirth usually leads to anxiety and apprehension, chronic pain tends to be associated with helplessness, depression, and irritability as well as interference with family function, work, or social interaction (Gatchel and Turk 1999). In addition to the large number of workdays that are lost as a consequence of it, chronic pain is the leading cause of invalidity in the age under-50s group and causes enormous costs for the health care system (Melzack and Wall 1994).

The IASP classification of pain is organized in five general categories: (a) the bodily system affected, (b) time characteristics, (c) intensity of pain (d) duration of pain, and (e) its presumed etiology. This classification lacks reliability especially in respect of the last characteristic. In addition, it neglects psychological factors that are only coded with respect to the presence of a psychiatric disorder or within the category 'psychophysiological dysfunction.' *ICD-10* as well as *DSM-IV* still adhere to the distinction between psychogenic-somatogenic or physical vs. somatoform pain, which must be viewed as obsolete given the large number of research findings emphasizing the importance of psychological factors in any type of pain, both acute and chronic (Gatchel and Turk 1999).

The biopsychosocial model of pain views pain as a complex response that can be described on the verbal-subjective, the motor-behavioral and physiological levels. Pain can be based on nociceptive input, but nociception is not a prerequisite of the experience of pain, which can be an exclusively central phenomenon, but always has physiological antecedents and consequences (Flor et al. 1990). The multiaxial classification of pain as proposed by Turk and his colleagues (cf. Turk and Rudy 1988) categorizes pain patients along both the somatic and the psychosocial dimensions. This classification has yielded three subgroups of patients in the psychosocial domain characterized as adaptive copers, interpersonally distressed, and dysfunctional, with significant differences in the course of the illness and response to treatment.

3. The Role of Learning in Chronic Pain

Both associative and nonassociative learning processes as well as social learning have been found to be of fundamental significance for the development of chronic pain. The repeated application of painful stimuli leads to reduced responsivity, i.e., habituation to the painful stimulation. In many states of chronic pain, sensitization rather than habituation occurs due to changes both at the level of the receptor and of the central nervous system (Woolf and Mannion 1999). Sensory information accelerates habituation and reduces activation caused by surprise, insecurity, and threat. This mechanism may underlie the effects reported in a large number of studies that support the positive results of preparatory information prior to acutely painful procedures such as surgery or bone marrow aspiration.

The most influential model of psychological factors in chronic pain was Fordyce's assumption that chronic pain can develop and be maintained due to operant conditioning of pain behaviors, i.e., overt expressions of pain. Fordyce (1976) postulated that acute pain behaviors such as limping or moaning may come under the control of external contingencies of reinforcement, and thus develop into a chronic pain

problem. Positive reinforcement of pain behaviors (e.g., by attention and the expression of sympathy), negative reinforcement of pain behaviors (e.g., by attention and the expression of sympathy), negative reinforcement of pain behaviors (e.g., the reduction of pain through the intake of medication or by the cessation of activity) as well as a lack of reinforcement of healthy behaviors could provoke chronicity in the absence of nociceptive input. Thus, pain behaviors, originally elicited by nociceptive input, may, over time, occur in response to environmental contingencies. This model has generated much research, which has not only confirmed the original assumptions made by Fordyce; it has also been shown that in addition to pain behaviors the subjective experience of pain, as well as physiological responses related to pain, are subject to reinforcement learning.

A special role has been assigned to the 'significant others' of chronic pain patients, who have high reinforcement potential. When solicitous, i.e., pain-reinforcing, spouses were present, several studies found that the patients were more pain-sensitive during acute pain tests than when the spouses were absent. The patients with nonsollicitous spouses did not differ whether the spouse was present or absent. These studies suggest that spouses can serve as discriminative stimuli for the display of pain behaviors by chronic pain patients, including their reports of pain intensity. Health care providers may also serve as discriminative cues influencing patients' responses. Solicitous responses by significant others can also lead to increased physiological pain responses in the patients, whereas the focusing on healthy behaviors by significant others can have positive effects on the pain experience.

Of equal importance is the operant conditioning related to the intake of pain medication. Patients are often told by their physicians or by well-meaning family members that they should not continue to take analgesic medication unless the pain increases to a point where it becomes intolerable (referred to as *prn* from the Latin, 'take as needed'). When pain medication is taken at that stage, both pharmacological and behavioral factors can contribute to the development of the misuse of medication and, in severe cases, even drug dependence. If analgesic medication is taken only at peak pain levels, the effect of the medication is less potent, and patients cycle between high and low levels of medication that facilitate the development of dependence. In addition, medication intake is negatively reinforcing, since the intake of medication ends an aversive state (pain). Subsequently, the pain-reducing behavior (use of analgesics) increases in frequency. Thus, both pharmacotherapists and behavioral psychologists recommend that analgesic medication should be taken not in a pain-contingent but rather in a time-contingent fashion, adapted to the specific pain level of the patient and to the half-life of the drug.

The negative reinforcement of activity levels is an important process in the development of disability. A specific activity, for example walking, is performed until pain sets in, at which point the activity is interrupted and replaced by rest. Subsequently, the pain will be reduced. The reduction of an aversive state—pain—negatively reinforces the cessation of activity. As was the case with the intake of analgesic medication, the cessation of activity has to be made dependent on the amount of activity achieved—quota-based (e.g., number of stairs climbed, distance walked) rather than on the amount of pain. Thus, the pain-reinforcing quality of rest is eliminated. This formulation supports the strategy of encouraging patients to perform activities to meet a specific quota, and not until pain is perceived as overwhelming.

The respondent conditioning model postulates that numerous, formerly neutral, cues can be associated with the experience of pain and can—over time—themselves elicit responses that lead to an increased pain response, and can create the experience of pain in the absence of nociceptive input. To illustrate this process, the patient may have learned to associate increases in muscle tension with all kinds of stimuli that were originally associated with nociceptive stimulation. Thus, sitting, walking, bending, or even thoughts about these movements, may elicit anticipatory anxiety and an increase in muscle tension. This fear of movement or 'kinesophobia' has been discussed as an important factor in the maintenance and exacerbation of chronic pain. Subsequently, patients may display maladaptive responses to any number of stimuli and reduce the frequency of performance of many activities other than those that initially reduced pain. Thus, although the original association between injury and pain results in anxiety regarding movement, over time the anxiety may lead to increased muscle tension and pain even if the nociceptive stimuli are no longer present. In addition, stress situations can increase muscle tension levels and cause sympathetic activation and may, thus, reinforce this process.

Many patients report that an acute pain problem evolved into chronic pain at a time where personal stressors co-occurred with the pain. Stress situations may serve as additional unconditioned stimuli and also as conscious stimulus for muscle tension increases, increased sympathetic activation, and subsequently pain. Nonoccurrence of pain is a powerful reinforcer for reduction of movement. Thus, the original respondent conditioning may be complemented by an operant process, whereby the nociceptive stimuli need no longer be present for the avoidance behavior to occur. People who suffer from acute back pain, regardless of the cause, may adopt specific behaviors (e.g., limping) to avoid pain and they may never obtain 'corrective feedback' because they fail to perform more natural movements. Reduction in physical activity may subsequently result in muscle atrophy and increased disability. In this manner, the physical

abnormalities proposed by biomechanical models of pain may actually be secondary to changes in behavior initiated through learning. Chronic pain patients tend to focus their attention on impending pain and subsequently avoid many types of activity, thus fostering the development of disability and depression. The release of endogenous opioids—the body's own analgesic system—may also be influenced by respondent conditioning as well as brain responses related to the experience of pain. Moreover, fear of pain and subsequent avoidance of activity is one of the best predictors of subsequent chronicity (Asmundson et al. 1999).

Response acquisition through the observation of others and modeling is an essential mechanism of learning new patterns of behavior. Children acquire attitudes about health and health care, and the perception and interpretation of symptoms and physiological processes from their parents and their social environment. They also learn appropriate responses to injury and disease, and thus may be more or less likely to ignore or over-respond to normal bodily sensations they experience. The culturally-acquired perception and interpretation of symptoms determines how people deal with illness; the sight of others in pain is an event that captures attention and may have survival value, may help to avoid experiencing more pain and help to learn what to do about acute pain. Modeling probably plays a part in the phenomenon of 'pain-prone families' families with a significantly elevated occurrence of pain problems (Whitehead et al. 1994). It was, for example, reported that children show the same pain syndromes as their parents currently have, rather than the pain problems their parents had in their own childhood. The large cultural variations in pain expression are also important. In common clinical practice, the acquisition or extinction of pain-related behavior by means of modeling has received little attention. However, there are occasional indications for the role of modeling in treating pain problems in children in burn units and in the treatment of postoperative pain.

Despite the great deal of data available on the modification of experimentally induced pain behavior by means of modeling in normal (healthy) subjects, there are few experimental results concerning chronic pain patients. Nor are there any longitudinal studies of the development of pain syndromes in 'pain-prone families.' Further investigation is necessary for the evidence of modeling as a factor in the development of chronic pain disorders.

4. Cognitive Factors and Pain

Cognitive-behavioral models of chronic pain emphasize that the evaluation of the pain experience by the patient greatly determines the amount of pain that is experienced as well as its negative consequences (Turk

et al. 1983). General assumptions that characterize the cognitive-behavioral perspective are: (a) people are active processors of information, not passive reactors; (b) thoughts (e.g., appraisals, expectancies) can elicit or modify mood, affect physiological processes, influence the environment, and serve as impetus for behavior. Conversely, mood, physiology, environmental factors, and behavior can influence thought processes; (c) behavior is reciprocally determined by the person and by environmental factors; (d) people can learn more adaptive ways of thinking, feeling, and behaving; and (e) people are capable and should be involved as active agents in change of maladaptive thoughts, feelings, and behaviors.

From the cognitive-behavioral perspective, people suffering from chronic pain are viewed as having negative expectations about their own ability to control certain motor skills such as performing specific physical activities (e.g., climbing stairs, lifting objects) that are attributed to one overwhelming factor, namely, a chronic pain syndrome. Moreover, chronic pain patients tend to believe that they have a limited ability to exert any control over their pain. Such negative, maladaptive appraisals about their situation and personal efficacy may reinforce the experience of demoralization, inactivity, and overreaction to noxious stimulation.

A great deal of research has been directed toward identifying cognitive factors that contribute to pain and disability. These have consistently demonstrated that patients' attitudes, beliefs, and expectancies about their plight, themselves, their coping resources, and the health care system affect their reports of pain, activity, disability, and response to treatment.

Pain, when interpreted as signifying ongoing tissue damage or a progressive disease, seems to produce considerably more suffering and behavioral dysfunction than if it is viewed as being the result of a stable problem that is expected to improve. A number of studies using experimental pain stimuli demonstrated that the conviction of personal control can ameliorate the experience of experimentally-induced nociception. Moreover, the type of thoughts employed during exposure to painful stimulation has been related to pain tolerance and pain intensity ratings. Catastrophizing thoughts have been associated with lower pain tolerance and higher ratings of pain intensity. In contrast, coping thoughts have been related to higher pain tolerance and lower pain intensity ratings.

Certain beliefs may lead to maladaptive coping, increased suffering, and greater disability. Patients who believe their pain is likely to persist may be passive in their coping efforts and fail to make use of available strategies, even when in their repertoire, to cope with pain. Patients who consider their pain to be an 'unexplainable mystery,' may negatively evaluate their own ability to control or decrease pain, and are less likely to rate their coping strategies as effective in controlling and decreasing pain.

Once beliefs and expectancies (cognitive schemata) about a disease are formed they become stable and very difficult to modify. Patients tend to avoid experiences that could invalidate their beliefs, and they adapt their behavior in accordance with these beliefs, even in situations where the belief is no longer valid (no corrective feedback is received to discredit this belief). For example, feeling muscular pain following activity may be caused by lack of muscle strength and general deconditioning and not by additional tissue damage.

Self-regulation of pain and its impact depends upon a person's specific ways of dealing with pain, adjusting to pain, and reducing or minimizing pain and distress caused by pain—their coping strategies. Coping is assumed to be manifested by spontaneously-employed purposeful and intentional acts, and it can be assessed in terms of overt and covert behaviors. Overt, behavioral coping strategies include rest, medication, and use of relaxation. Covert coping strategies include various means of distracting oneself from pain, reassuring oneself that the pain will diminish, seeking information, and problem solving. Studies have found active coping strategies (efforts to function in spite of pain, or to distract oneself from pain such as activity, or ignoring it) to be associated with adaptive functioning; and passive coping strategies (depending on others for help in pain control and restricted activities) to be related to greater pain and depression. However, beyond this there is no evidence supporting the greater effectiveness of one active coping strategy compared to any other (Fernandez and Turk 1989). Specific coping strategies need not always be adaptive or maladaptive. It seems more likely that different strategies will be more effective than others for some people at some times, but not necessarily for all people all of the time, or even the same person at different times.

5. Pain and Affective Factors

The affective factors associated with pain include many different emotions, but they are primarily negative in quality. Anxiety and depression have received the greatest amount of attention in chronic pain patients; however, anger has recently received considerable interest as an important emotion in chronic pain patients. Research suggests that from 40 to 50 percent of chronic pain patients suffer from depression (Romano and Turner 1985). There have been extensive and fruitless debates concerning the causal relationship between depression and pain. In the majority of cases, depression appears to be the patients' reaction to their plight. The presence of depression is closely related to the feelings of loss of control and helplessness often associated with pain.

Several investigators have also found a close association between fear of pain and dysfunctional

coping. In addition, high comorbidity between anxiety disorders and pain seems to be present. Muscular hyperreactivity to stress seems to be closely associated with fear of pain.

Anger has been widely observed in individuals with chronic pain. The internalization of angry feelings seems to be strongly related to measures of pain intensity, perceived interference, and reported frequency of pain behaviors. Anger and hostility are closely associated with pain in persons with spinal cord injuries. Frustrations related to persistence of symptoms, limited information on etiology, and repeated treatment failures along with anger toward employers, the insurance, the health care system, family members, and themselves, also contributed to the general dysphoric mood of these patients. The impact of anger and frustration on exacerbation of pain and treatment acceptance has not received adequate attention. It would be reasonable to expect that the presence of anger may serve as an aggravating factor, associated with increasing autonomic arousal, and having the effect of blocking motivation and acceptance of treatment oriented toward rehabilitation and disability management rather than cure, which are often the only treatments available for chronic pain.

6. Biobehavioral Perspective

A biobehavioral perspective of chronic pain needs to consider the factors discussed above and their mutual interrelationships in the explanation of chronic pain. The existence of a physiological disposition or diathesis is one important component. This predisposition is related to a reduced threshold for nociceptive stimulation and can be determined by genetic factors or acquired through early learning experiences. For example, Mogil (1999) showed that large genetic variations in individual pain sensitivity exist. Very impressive evidence for the role of early traumatic experience comes from the work of Anand et al. (1999), who showed that minor noxious experience in neonate rats leads to dramatic alterations (sensitization) in nociceptive processing in the adult organism. A further component of the biobehavioral model is a response stereotype of a particular bodily system, such as exaggerated muscular responses of the lower back muscle to stress and pain that is based both on the diathesis and on aversive experiences present at the time of the development of the response. These aversive stimuli may include personal or work stress or problematic occupational conditions and will lead not only to painful responses but also to avoidance behaviors and associated maladaptive cognitive and affective processes. The cognitive evaluation of these external or internal stimuli is of great importance in the pain response, as discussed above.

7. Memory for Pain

An important maintaining factor in this chronicity process is the development of pain memories. These pain-related memories may be explicit or implicit and may subsequently guide the patient's experience and behaviors (Erskine et al. 1990). For example, pain patients have a tendency to remember preferentially negative and pain-related life events and show a deficit in the retrieval of positive memories. The experience of chronic pain also leads to the development of somatosensory pain memories for example, an expanded representation of the affected body part in the primary somatosensory cortex. This expanded cortical representation is accompanied by increased sensitivity to both painful and nonpainful stimuli, and may be further enhanced by learning processes or attention to painful stimulation. A dramatic example of a learned memory for pain has been found in phantom limb pain patients (Flor et al. 1995). In upper extremity amputees, the magnitude of the phantom limb pain was found to be proportional to the amount of reorganization in the primary somatosensory cortex, namely, the shift of the cortical mouth representation into the area where the amputated limb was formerly represented. The brain obviously maintains a memory of the former input to the deafferented area. Subsequently, stimulation stemming from areas adjacent to the deafferented zone elicit sensations and pain in the now absent limb. Phantom sensations and cortical reorganization are absent in congenital amputees. The focus of the biobehavioral perspective is thus on the patient and not just on the symptoms or the underlying pathology. This focus also requires that the treatment of the patients be tailored not only to medical factors, but that it incorporates psychosocial variables that may often be predominant in states of chronic pain (see *Chronic Pain: Models and Treatment Approaches*).

8. Future Perspectives

At the end of the twentieth century, there has been an enormous increase of research in the neurosciences, where the mutual interactions of molecular and genetic as well as neuronal and behavioral variables have begun to be examined. This integration of the psychosocial and biomedical perspective is much needed and will bring substantial advances in our understanding of the phenomenon of pain. A further important development is the recent finding in neuroscience that the adult brain is enormously plastic and that learning processes as well as training measures have great impact on these plastic changes (Recanzone 2000). This opens the door for new approaches to treatment. It will also aid in delineating and eliminating the factors that lead to resistance to the treatment of chronic pain syndromes.

Pain, Management of

1. The Physiology of Pain

Pain is defined as 'an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.' It is the most common complaint voiced by patients when they seek medical attention. The ability to perceive pain serves a protective function for the individual. The sensation warns of impending injury and elicits reflex and behavioral responses that keep tissue damage to a minimum (see Livingston 1998, Melzack 1973, Rey 1995).

In many instances, noxious stimuli applied at the skin surface (blunt trauma, burns, a surgical incision) serve to activate pain receptors. These are special nerve cells, termed nociceptors, which convert (transduce) the energy delivered at the periphery to neural impulses. Transduction is the first of four processes allowing the energy that produces noxious stimuli to result eventually in the perception of pain. Once this initial energy is transduced into electrical impulses, nerves carry the stimulus to higher levels of the nervous system. This activity is termed *transmission*, and it allows the noxious stimuli to be conveyed from the skin to the spinal cord as a series of electrical messages. As the signals arrive in the dorsal horn of the spinal cord, they are altered by other impulses within the cord and by descending impulses from higher neural centers. This is termed *modulation*. These modified and processed impulses continue upward towards the brain and allow a person to experience the perception of pain. This is an individual and highly subjective phenomenon. Another person can not reliably measure it. There is no objective appraisal of the sensation that an individual calls pain.

An understanding of the four events is critical to an appreciation of the mechanisms by which pain can be managed. The physician targets therapies to prevent the electrical signals from reaching the cortex and limbic systems of the brain where pain enters a person's consciousness. Thus treatments are aimed at interrupting pain information as they are transduced to nerve impulses; transmitted towards the spinal cord; and modulated within the cord; or by modifying the neural impulses as they enter the brain where the actual perception occurs.

Minimizing the pain a patient perceives has value on a number of fronts: humanitarian, physiologic, functional, and economic. Progress made in this area of medicine was begun by anesthesiologists in the 1980s when they began to organize services to treat surgical inpatients immediately following operations. These activities were logical extensions of the work they already performed during surgery. Acute pain services are now well established divisions of most hospitals in the United States.

Workers in the field of pain management divide pain into three separate categories: acute, chronic non-malignant, and cancer pain. Management varies depending on the etiology. Acute pain is experienced following trauma, elective surgical procedures, or the exacerbation of chronic medical conditions (e.g., sickle cell crisis). Tissue damage initiates a cascade of physiological and behavioral changes. These have the potential to progress into chronically painful states if left unattended.

1.1 Acute Pain

Mechanisms to manage operative and postoperative pain focus on the delivery of medications to specific sites within the body. Local anesthetics, such as lidocaine can be injected under the skin prior to an incision. This is exemplified by the use of a nerve field block performed immediately before an inguinal hernia repair. The medication is injected at the site of the surgery and given time to work. Local anesthetics act by blocking the conduction of impulses down nerve fibers. These nerves, then, cannot transmit to the central nervous system (CNS) the information that tissue damage (the surgical incision) is occurring. Since the CNS never receives the nerve impulses, the patient does not perceive pain.

More sophisticated techniques include the deposition of local anesthetics into areas wherein numerous nerves converge. Because these areas are densely packed with passing nerve fibers, a small amount of anesthetic can effectively block pain messages from a large segment of the body. Examples of these procedures include brachial plexus (an area of convergent nerves from the arm and hand) blockade prior to hand surgery, and epidural (a space just outside the spinal cord) blockade, which is used to blunt the intensity of labor pains prior to childbirth. One problem of the use of local anesthetic is that these agents are generally fairly short-acting. The duration of the blockade can be prolonged by co-injection of agents which decrease blood flow in the immediate area of injection. Less blood flow to the area of blockade means the anesthetic agent is taken away by the bloodstream more slowly, prolonging the presence, and effect, of the local anesthetic. Another method physicians use to prolong local anesthetic action is to pump anesthetic continuously into the needed area through a plastic tube or catheter that has been inserted into that region. This technique allows pain control for very long periods of time. For example, a catheter placed in a position that blocks pain from the chest (thorax) can be used to manage pain related to chest (thoracic) surgery for five days following the operation. A catheter is placed at the appropriate level within the epidural space and taped to the patient's skin. An infusion pump is programmed to deliver local anesthetic, opioid (such as morphine), or a mixture of both agents at an hourly

rate. When the mixture of agents is used, very dilute concentrations of each are employed. Inhibiting the transmission and modulation of nerve impulses with different classes of agent allows for synergy of effect. Excellent control of very strong pain can be achieved with the use of epidural catheter placement and the constant infusion of analgesic mixtures. Sensitivity of the affected area returns quickly when the drugs are stopped.

Unfortunately, local anesthetics block not just pain sensors, but all nerves. Thus, they produce a profound numbness and, in some cases, difficulty in moving muscles. In addition, they are only active for a short time, or require the placement of a catheter near the nerves to be affected. Therefore, other means are necessary to deal with more long-duration pain. For example, systemic medications can be delivered intravenously to blunt the perception of pain. Newer technology in the form of microprocessors and physically small infusion pumps have made the management of acute, post-surgical pain more precise. Patient-controlled analgesia (PCA) pumps provide an infusion of morphine or similar drugs at a constant background rate. This is usually 1 or 2 milligrams of morphine over the course of an hour. Furthermore, a patient can activate the pump to deliver additional morphine by the push of a button. Dosage is often 2 milligrams which can be repeated every sixth minute. This machinery allows the patient substantial control of how much morphine he or she is receiving so that the dose delivered matches his or her needs. The background infusion guarantees that some analgesia is delivered to the bloodstream to compensate for normal clearance of the analgesic by the liver and kidneys. The patient-controlled aspect enables the patient to raise immediately the blood level of the morphine should the perception of pain increase in intensity. This commonly correlates with the patient's degree of physical activity and can often be anticipated. A patient who is comfortable while lying down may feel pain when getting into a chair. In this instance, self-dosing permits the level of opioid to match the need for analgesia on a minute by minute basis. Since the pump must be activated before delivering additional medication, the risk of overdosage is minimized. Patients who are sleepy from a high serum level of morphine will not push the button for additional medication. In some instances, morphine is not the appropriate agent to use as it produces significant side-effects in some patients. In these cases, other opioids such as fentanyl, demerol, or dilaudid can be used. Individual preferences and the reactions to treatment are used to guide further therapy.

Progress has been made in the development of non-steroidal, anti-inflammatory drugs (NSAIDs). Aspirin, acetomenophin, and ibuprofen are well known examples of these drugs. NSAIDs are a class of medications that diminish swelling and decrease the perception of pain. They act both at painful sites and

in the CNS by inhibiting the enzyme cyclo-oxygenase. Intramuscular and intravenous NSAIDs have been developed so that patients in the immediate post-operative period and still unable to consume pills can benefit from the agents. The newest drugs in the class are highly selective for the desired effects and show little of the side effects which have been problems with the long-established NSAIDs. Patients are often offered intravenous doses of an NSAID in the post-operative period if they experience pain breaking through despite continuous epidural infusion of local anesthetics (see above).

New approaches to delivering analgesic drugs into the body are also being developed. Intranasal (nasal spray), pulmonary (inhaler), and transbuccal (under the tongue) routes of opioid delivery are all being researched with the goal of providing immediate pain relief. A transdermal system of the opioid fentanyl delivery is currently available but is rarely used to treat acute pain. The skin directly under the sticky transdermal patch absorbs fentanyl which acts to gradually release the medication over hours or even days. Unfortunately, changing the blood level of a drug is slow when using transdermal patches, and so the risk of drug overdose in this patient population is higher. Transdermal patches are rarely used in the post-operative phase of patient care, but are more commonly used for chronic and cancer-related pains.

1.2 Chronic Pain

Chronic, noncancer related pain affects 75 million Americans. Pain decreases the quality of life of these people and impairs their ability to work productively. Chronic pain is defined as pain that persists for longer than the expected time frame for healing, or pain associated with progressive diseases. Many patients suffer from clinical syndromes for which there are no x-ray, laboratory, or other physical evidence of something wrong, and so diagnoses rely on clinical criteria alone. These syndromes include many kinds of headache, myofascial pain syndromes (for example chronic jaw pain), fibromyalgia, neuropathic pain, low back pain, and central pain syndromes. Little is known about the underlying causes of these syndromes. Patients do, however, present with the complaint of pain. Other patients have disorders that are well described, e.g., osteoarthritis, but for which we have no cure.

Irrespective of the cause, the effects of chronic pain on a patient's life tend to be more pervasive than that of acute pain. Chronic pain affects all of the patient's social relationships, personality, and mood. Typically, people with chronic pain tend to have sleep disturbances, generalized fatigue and a decrease in their overall level of functioning. In many, the perception of pain cannot be eliminated, only lessened. The goal becomes one of managing the pain as well as is

possible while improving the person's involvement and function in his life. To this end, a multidisciplinary approach that focuses on all aspects of the patient's condition seems to have the best results. The core team consists of a pain management specialist along with representatives from pharmacy, physical and occupational therapy, psychology, and internal medicine. The care team tailors the care plan according to the needs of the individual patient. An open discussion of goals is necessary to assess objectively if progress is being made. Often the goals of productive activity and a return to work are stressed.

Treatment of chronic, non-cancer related pain conditions requires the use of analgesic medications. NSAIDs are often the mainstay of therapy. Long-term use of the agents carries the risk of easy bruising, renal dysfunction, and the development of gastric ulcers. As mentioned above, the newer NSAIDs help to limit these side effects. Patients must be warned of these complications and followed closely. The agents are potent analgesics that improve the quality of life for those who suffer from many chronic pains, especially arthritis.

Long-acting opioids can effectively control pain in a subset of chronic pain patients. Patients must be assessed carefully before the start of therapy. The potential for substance abuse or addiction must be considered even though they are not commonly encountered in patients with chronic pain. Guidelines exist which help to clarify the conditions under which the prescribing of opioids is appropriate in the treatment of chronic pain states. Common adverse side effects include constipation, pruritis, sedation, and impaired cognition. Although most of the side effects diminish over time, constipation usually persists and must be treated.

Antidepressants are effective in the treatment of many painful conditions. Their mechanism of action is unclear, but they seem to act by increasing the levels of norepinephrine and serotonin at the nerve synapses of the central nervous system. In addition to their direct effect in diminishing the perception of pain, the agents also are useful as an aid to sleep. Patients take the medication in the late evening and report improvements in their ability to fall asleep and stay asleep throughout the night. The agents have the potential for bothersome side effects which include dry mouth, blood pressure changes, urinary retention, and, rarely, heartbeat irregularities. The drugs are used as a part of an integrated care plan and improve the overall quality of the patient's life.

Anticonvulsants are effective in the treatment of many chronic pain states. The mechanism of action is again unclear. They may suppress the production of nerve impulses in nerve cells that are critical in developing the perception of pain. A newer anticonvulsant, gabapentin, provides symptomatic relief with fewer side effects than older drugs of this class. Patients notice sedation and episodes of dizziness

when they begin taking the drug, but acclimate to it over a matter of days.

More invasive methods for the treatment of chronic painful states have been tried with no proven benefit. Cutting the spinal cord pathways that transmit pain messages to the brain produces temporary (6–12 month) pain relief, but the pain then returns, sometimes worse than ever. The direct injection of local anesthetics into the most painful muscle areas of myofascial pain syndrome seems to provide symptomatic relief for some of the patients. The procedures have not been tested in a randomized or blinded manner, however, and the benefits may be the result of the placebo reaction. Epidural steroid and local anesthetic injections have also been used for those who complain of vague lower back pains. The steroids are known to decrease inflammation, edema, and decrease the synthesis of prostaglandins (substances known to mediate the perception of pain). Again, the patients often report benefits in their symptoms, but there is no clear mechanism to explain the improvement.

1.3 Cancer Pain

The prevalence of cancer pain ranges from 30–50 percent of patients who are undergoing active treatment for solid tumors. The number climbs to 80–90 percent for those who suffer from advanced forms of the disease. Approximately three-quarters of these chronic pain syndromes result as a direct effect of the tumors themselves. The remaining complaints are related to the therapies administered to manage the primary or metastatic aspects of the cancer.

Neoplastic (tumor) invasion of bone or connective tissue is a major cause of severe pain. The spine is the most common site of bony metastasis. Many patients with cancer have back pain because the cancer has spread to this bony area. Continued growth of the tumor causes spinal cord and nerve root compression. Cancerous growth in this area will result in pain, as well as paralysis and the loss of bowel and bladder control for the patient. Obstruction and compression of the bowel produces intense visceral complaints. Patients will present with persistent abdominal pain, constipation, nausea, and vomiting. The tumor will have to be surgically removed, sometimes resulting in nerve injury-induced (neuropathic) pain. Radiation, frequently used to shrink tumors, can cause fibrosis, which may in turn damage peripheral nerve and central nervous system tissue. These injuries frequently cause a chronic neuropathic-type pain, along with tingling and numbness in the area.

The mainstay for management of cancer-related pain is the use of oral analgesics leading up to opioids in progressively larger doses as the disease progresses. The World Health Organization has devised an algorithm for use of oral analgesics that matches the intensity of the pain with the potency of the medication

prescribed. Although the oral route is commonly used, the transdermal approach has gained popularity because of the ease of administration. Each patch is worn for approximately three days before it must be replaced. The system has the advantage of infrequent dosing, but as mentioned above, keeping the right blood level is difficult. Most practitioners will start the patient with a relatively low dose of transdermal fentanyl, but then give the patient morphine pills to use as needed in order to supplement the relief provided by the patch. Individualization is the key to successful treatment. Each patient must be evaluated and a treatment plan formulated based on that individual's needs. In some, radiation and chemotherapy will effectively reduce the tumor mass and diminish pain. In others, there will be little hope of shrinking the tumor and the only recourse is to make these patients as comfortable as possible. This 'end-of-life' strategy is termed palliative care.

The success of continuous infusions of local anesthetics in the operating room and immediately postoperatively has prompted the developments of portable and reprogrammable infusion pumps for use by cancer pain patients. In some cases, these pumps are implanted under the skin. Pumps allow the continuous infusion of strong opioids through catheters to sites directly within the spinal canal, either epidurally or directly onto the spinal cord itself (intrathecally). The opioids act directly on nerve cells in the spinal cord to inhibit pain messages, resulting in profound pain relief. The epidural or intrathecal catheters are tunneled under the skin and attached to a pump that has within it a reservoir to hold the opioid. The machinery is programmed to deliver a preset amount of opioid as needed to provide adequate pain relief. On a regular basis, the reservoir is refilled to allow for continuous pain relief as needed.

The most invasive therapies used for those with advanced stages of cancer involve the use of ablative surgical or anesthetic procedures. As mentioned above, spinal cord incisions can produce profound pain relief. Because pain recurs over the long term, however, this procedure is only used near the end of life. Pure alcohol is toxic to nerves. Thus, another fairly drastic procedure involves the injection of pure alcohol into individual nerves of the spinal cord to destroy those nerves carrying pain messages to the CNS. In these ways, patients near the end of their life can achieve a degree of pain relief that is not attainable with less invasive measures.

Cancer pain must be viewed in the context of a progressively advancing illness. The optimum management allows for the treatment to match the intensity of discomfort. The smallest dose of the most benign medication that provides relief is used first. When the intensity of pain increases, stronger medications and more invasive techniques are used. In this way, a comprehensive range of agents and techniques are used in sequence to provide optimal pain relief.

2. *Novel Approaches to the Relief of Pain*

2.1 *Transplantation*

Recent laboratory studies have shown that transplantation of adrenal medullary tissue or of isolated chromaffin cells into CNS pain modulatory regions can reduce pain sensitivity in both acute and chronic (including neuropathic) models in rats. The analgesia produced by these transplants probably results from the release of both opioid peptides and catecholamines such as adrenaline and noradrenaline since it can be blocked or attenuated by both opiate and adrenergic blockers. Studies indicate that even over long periods there is no apparent development of tolerance.

Positive results have also been obtained in preliminary clinical studies using transplants of human adrenal gland pieces to relieve intractable cancer pain in 25 patients. Pain scores and morphine intake were measured prior to transplantation and at regular intervals following the graft implantation. Biochemical assays were performed on a sample of the patients' cerebrospinal fluid (CSF) throughout the study to assess levels of catecholamine and met-enkephalin (an opiate manufactured by the body) as an indication of graft viability. Sixteen out of 20 patients reported long lasting pain relief from these transplants (more than a year in some patients). Narcotic analgesic (e.g., morphine) intake was eliminated, reduced or at least stabilized in all patients who completed the study. These studies indicate that even over long periods, there is no development of opiate tolerance. Histological data was obtained at autopsy from some patients who had transplants for over a year. Study of the spinal cord revealed intact adrenal medullary tissue fragments distributed over several levels, with no signs of inflammation or rejection. The results of these clinical trials are encouraging over all and suggest that chromaffin cell transplants can provide relief from intractable pain. With appropriate modifications to optimize graft preparations and survival, it is likely that this approach can become an alternative means of controlling pain refractory to traditional pharmacotherapies (see Michalewicz et al. 1999, Lazorthes et al. 2001).

2.2 *Gene Therapy*

Another new approach to chronic pain is that of gene therapy. This method so far is only at the animal testing stage, but appears to be very promising. Different approaches have been taken to change the genetics of nerve cells that are involved in pain so that that function of the cells is disrupted. The first of these involves the injection of 'antisense' on to the spinal cord. Genes are essentially codes that cells read, and which cause the cell to make a particular chemical, as,

for example, a protein. Some of these chemicals are critical to the transmission of pain information from one cell to another. Antisense is essentially the code for one of these chemicals, but in reverse order. This effectively disrupts the cell's ability to read the 'real' gene and so inhibits its ability to make the chemical. If antisense is injected on to surface of the spinal cord, some of it will find its way into the correct pain neurons and so, to a greater or lesser extent, inhibit transmission of pain messages (see Peric et al. 2001).

Applying antisense to spinal cord nerve cells appears to work in animals, but is somewhat nonselective as to which cells it goes into, and is not very efficient in getting it there. For this reason, other researchers have been working on ways to use viruses as 'vectors' to carry genes that may inhibit pain transmission into the nerve cells that carry that information. One method involves putting the gene for naturally-occurring opioids into either adenoviruses (the kinds that causes the common cold) or herpes viruses (the kinds that causes cold sores). These viruses are very efficient at getting these genes into spinal nerve cells and produced long-lasting analgesia in animals. The adenovirus is injected directly into the spinal cord itself, whereas the herpes virus is placed near pain receptors outside the CNS where it is taken up and carried back to the spinal cord. The herpes virus approach has also been used to carry antisense directly into the pain-conducting nerves (see Wilson et al. 1999). All of these approaches present new and exciting approaches to the treatment of chronic pain.

Pain, Neural Basis of

The term 'pain' has several different connotations that are a potential source of confusion in its usage. The most frequent of such confusions consists in an equivocation of first- and third-person aspects of the target phenomenon (Metzinger 2000). There is the consciously experienced subjective qualitative aspect of pain. In this sense, to feel pain indicates a state of suffering. This aspect is only experienced from the first-person perspective and, arguably, is not directly accessible for empirical research operating from an objective, third-person perspective. Third-person aspects of pain are constituted by its neural underpinnings (e.g., the minimally sufficient neural correlate of the subjectively experienced, conscious quality of pain) and the functional properties, that is, the causal role, played by them in generating overt behavior, internal reactions, the formation of memories, etc. In this sense, pain is the percept that results from the activation of a specific sensory system, the nociceptive system, which is activated by external stimuli that threaten the integrity of the body, and by internal states of tissues such as an inflammatory process. As such, pain is a sensory experience similar to the experience of hearing a sound or tasting food as a consequence of the activation of the auditory, gustatory, or olfactory system. A comprehensive theory of pain will have to do justice to both aspects, the third-person and first-person aspects, of pain.

Since the 1970s the following definition by the International Association for the Study of Pain has gained widespread acceptance (Merskey et al. 1979):

- Pain is an unpleasant sensory and emotional experience

- associated with actual or potential tissue damage
- or described in terms of such damage.

This definition emphasizes that pain has several components, including at least a sensory one and an affective one. In most instances, pain is not a generalized feeling (*Allgemeingefühl*) such as hunger and thirst, but a localized sensation. The capacity to locate pain is due to the encoding of spatial information in the nociceptive system. Likewise, fluctuations in the perceived intensity of pain can be related to intensity coding in the nociceptive system. The discriminative power and the precision of stimulus encoding in the nociceptive system have traditionally been underestimated. In addition to this sensory-discriminative component, pain almost inevitably encompasses an affective component, mostly of a negative hedonic

quality, which is not a simple function of sensory intensity or quality. While pain may be a particularly unpleasant sensory experience, affective components are present in other sensory systems as well: a person may like or dislike a certain type of music, and a meal may have a pleasant or unpleasant taste. These affective or emotional components of sensory experience provide powerful drives to direct behavior (e.g., withdrawal, guarding, or avoidance behavior). The unpleasant emotional aspects of pain perception are therefore called the affective-motivational component of pain. The aim of this article is to present the neural basis of both components of pain from the point of view of sensory physiology. In the last section, an outlook will be given as to how sensory physiology may provide hints to understanding the subjective experience of feeling pain.

1. *The Nociceptive System*

Many tissues such as the skin, mucous membranes, muscles, joints, bones, and parts of the viscera (with the notable exception of the brain itself) are innervated by free endings of thin primary afferent nerve fibers (Raja et al. 1999). The adequate stimulus to activate these nerve endings is a strong mechanical or thermal stimulus, or one of a variety of chemicals that are either applied from the outside (as with a nettle sting or the application of hot peppers to mucous membranes) or generated within the tissue (such as bradykinin, serotonin, histamine, prostaglandins, etc.). Because they respond to several stimulus modalities, these nerve endings are said to be polymodal. The common denominator of these stimuli is that they indicate either actual or impending tissue damage. Sherrington summarized this concept in the term 'noxious stimulus,' and the sensory system that processes information on noxious stimuli is called the nociceptive system. More recently it was found that polymodality does not depend on actual tissue damage but may also be a property of the ion channels present in free nerve endings. Many nociceptive nerve endings express the so-called vanilloid receptor channel VR1 (Caterina and Julius 1999), which can be activated by a physical stimulus (heat), and by both exogenous (capsaicin and other hot spices) and endogenous chemicals (anandamide and other derivatives of membrane lipids).

Some primary nociceptive afferents (A-fibers) conduct nerve impulses relatively rapidly (about 20 ms^{-1}), because of the saltatory impulse conduction that is enabled by the presence of a myelin sheath; most of the primary nociceptive afferents are unmyelinated C-fibers and conduct slowly (about 1 ms^{-1}). A-fibers are involved in rapid behavioral responses and in motor reflexes. C-fibers are involved in slower signaling processes, including the perception of a delayed 'second pain' after a single brief stimulus such as a

pinprick, changes in the sensitivity of the nociceptive system (see Sect. 4), control of local blood vessels, and trophic functions (Holzer 1992).

Primary nociceptive afferents make synaptic contact with second-order neurons in the dorsal horn of the spinal cord. Some nociceptive specific neurons have no other input, whereas another class of neurons receives convergent input from touch receptors in the skin. These neurons encode a wide range of mechanical stimulus intensities and are therefore called wide-dynamic-range neurons (Willis 1985). Spinal nociceptive neurons are subject to modulation by descending pathways from the brain stem, which are mostly inhibitory and utilize endogenous opioids, nor-adrenaline, and serotonin as neurotransmitters. The net result of primary afferent inputs, descending modulation, and local interactions in the spinal cord dorsal horn is then projected to spinal motor nuclei in the ventral horn, spinal autonomic nuclei in the lateral horn, to the brain stem and to the contralateral somatosensory thalamus.

Via the spinoreticular and spinomesencephalic tract projection to the brain stem, noxious stimuli may activate autonomic reflex centers of the cardiovascular and respiratory system, the descending inhibition of the spinal cord dorsal horn, and the ascending reticular activating system (ARAS) that projects to the cerebral cortex. These projections are the neural basis for many autonomic reflexes elicited by pain, for the fact that one pain may inhibit another pain, and for the strong arousal reaction to painful stimuli.

Via the spinothalamic tract, the nociceptive pathways reach two groups of nuclei in the thalamus (Craig and Dostrovsky 1998). The lateral group is situated in the ventrobasal complex and is identical to the relay station of the tactile system. These thalamic nuclei project to the primary and secondary somatosensory cortex (SI and SII), and to the insula. The medial group is mostly situated within the white matter of the thalamus (intralaminar nuclei). These thalamic nuclei project to the anterior cingulate gyrus, the basal ganglia, and also nonspecifically to wide parts of the cerebral cortex. Since its original suggestion in the late 1960s (Melzack and Casey 1968), the concept that the lateral system processes the sensory discriminative component, and the medial system the affective-motivational component of pain, is still a valid concept (Treede et al. 1999).

2. *Sensory Discriminative Functions*

The sensory discriminative component of pain may be divided into at least three aspects: stimulus localization, intensity discrimination, and quality discrimination. The human capacity to perceive the location of tissue damage is used in everyday medical practice, when doctors ask the question 'where does it hurt?' Sometimes, tissue damage and perceived pain are in

different locations, as in the case of a myocardial infarction, which may cause pain in the left arm. This phenomenon (referred pain) is due to convergence of visceral and cutaneous afferents in the spinal cord. The activity of the spinal neurons does not reveal the afferent source, and higher centers are assumed to project the resulting sensation along the more common pathway from the skin. Because of the mislocalization of pain originating from damage to the viscera and the precise localization of tactile stimuli at the fingertips, localization of noxious stimuli has traditionally been ascribed to simultaneous activation of the tactile system. Tactile acuity, however, rapidly drops outside the 'foveal' areas of the fingertips and lips. On the back of the hand, sequential tactile stimuli must be about 1 cm apart to be perceived as being given to separate locations. When laser-radiant heat pulses (which do not activate tactile afferents) are given to the back of the hand, the sequential spatial discrimination threshold is also about 1 cm (Schlereth et al. 2001).

These psychophysical findings demonstrate that the nociceptive system in humans provides sufficient spatial information to account for our capacity to know where it hurts. What is the neural basis for this capacity? Receptive fields of nociceptive neurons show somatotopic organization in the spinal cord dorsal horn (Woolf and Fitzgerald 1986), lateral thalamus (Albe-Fessard et al. 1985), and the primary somatosensory cortex (Kenshalo and Willis 1991). Receptive field sizes in SI are smaller than in the spinal cord and thalamus, possibly due to lateral inhibition, and match the pain localization capacity. Thus, all existing evidence favors the view that SI is involved in stimulus localization for the nociceptive system as well as the tactile system. Indirect evidence for this concept is provided by studies in humans that use measures of brain perfusion as parameters of activation (by positron emission tomography: PET). These studies suggest that only tasks with a stimulus-localization component activate SI, whereas studies with fixed stimulus location do not (Treede et al. 1999).

The capacity to encode different intensities of noxious stimuli is one of the criteria for identifying nociceptive neurons (Willis 1985). Intensity coding has been demonstrated for nociceptive neurons in SI and to a certain extent in SII, but also in medial thalamic nuclei. Intensity coding is a poor criterion for identifying neurons involved in sensory discriminative aspects of pain, because the affective-motivational component of pain also depends on stimulus intensity. In a study that demonstrated the different relative unpleasantness of experimental painful stimuli, perceived intensity and unpleasantness were both nevertheless related to stimulus intensity (Rainville et al. 1992).

Pain may have different qualities such as burning, stinging, or aching. Neither the number of subjectively discriminable qualities nor their neural basis are known with sufficient precision. The polymodality of primary nociceptive afferents seems to contradict the

capacity for quality discrimination, but the response profiles to different noxious stimuli differ between different afferents. Quality discrimination in the nociceptive system is therefore likely to be due to a population code, similar to the encoding of the taste qualities in the gustatory system.

Current evidence supports the traditional view that the lateral nociceptive system subserves the sensory discriminative component of pain. Different aspects of this pain component (detection, localization, intensity discrimination, quality) may be processed in parallel by separate pathways. In contrast to traditional views, there is no evidence that the tactile system participates in any of these functions. Thus, nociception is established as a sensory modality within the somatosensory system.

3. Affective Motivational Functions

The affective-motivational component of pain sensation encompasses several aspects that are closely related: the negative hedonic quality and emotional reactions, an increase in the arousal level and stimulus-related selective attention, and the drive to terminate the stimulus causing this sensation. Some of these functions can be considered second-order sensory processing, whereas the latter is a premotor function. The affective-motivational component of pain is classically associated with the medial nociceptive system, which in turn is connected to the limbic system.

One part of the medial nociceptive system, the anterior cingulate cortex, has recently gained much publicity, because virtually all PET studies of acute pain gave evidence of activation in that area, including one study in which pain was elicited as an illusion by the interaction of two nonpainful stimuli (Craig et al. 1996). Electrophysiological recordings in humans also show activity in this area (Treede et al. 1999). The anterior cingulate cortex is a functionally heterogeneous brain area that has been implicated in the integration of affect, cognition, and response selection in addition to aspects of social behavior (for review, see Devinsky et al. 1995). Passive functions (emotion, attention) are represented more frontally, whereas a premotor part of the anterior cingulate cortex is situated more posteriorly, below the supplementary motor area. It is still debated, whether the anterior cingulate cortex may contain a nociceptive-specific area, or whether painful stimuli nonspecifically recruit several parts of the large cingulate gyrus.

The affective-motivational component of pain may also be processed in the insula. The contralateral insula was activated almost as frequently in human PET studies of acute pain as the anterior cingulate cortex (Casey and Minoshima 1997). Microstimulation in a thalamic nucleus that projects to the insula elicited pain with a strong affective component only in those patients who had previously experienced such

pain either due to panic attacks or due to angina pectoris (Lenz et al. 1995). These observations suggest that the insula may be part of a sensory limbic projection pathway for pain sensation. The insula projects to the amygdala (Augustine 1996), which is a part of the limbic system that is associated with emotions.

4. Plasticity of the Nociceptive System

As in all other sensory systems, the repeated presentation of noxious stimuli or the exposure of the nociceptive system to stimuli of long duration may lead to a reduction in the intensity of the evoked response (habituation and adaptation). A unique property of the nociceptive system is that under many circumstances the prior presentation of the adequate stimulus may actually enhance subsequent responses (Treede et al. 1992). This enhancement is called sensitization and it may occur at both the peripheral

terminals of primary nociceptive afferents and within the central nervous system. Sensitization refers to a leftward shift in the function that relates the neural response to stimulus intensity. It is characterized by a drop in threshold and an increase in the response to suprathreshold stimuli. Spontaneous activity may also result from sensitization.

The perceptual correlate of sensitization is hyperalgesia, which is characterized by a drop in pain threshold and an enhanced painfulness of supra-threshold stimuli. Even minor tissue injury elicits a transient state of hyperalgesia, both of the injured tissue itself (primary hyperalgesia) and in surrounding uninjured skin (secondary hyperalgesia). Primary hyperalgesia is characterized by a lowered pain threshold for both mechanical and heat stimuli. Secondary hyperalgesia is characterized by a lowered pain threshold for mechanical stimuli only.

In primary hyperalgesia, the heat pain threshold may drop below the normal body temperature, which then starts to act as an adequate stimulus for the

Figure 1

Major components of the nociceptive system. Free endings of A δ - and C-fibers in skin and other tissues are activated by actual or impending tissue damage (noxious stimuli). At the first synaptic relay station in the spinal cord, their signals interact and are strongly modulated by segmental and descending connections. After another synaptic relay station in lateral thalamic nuclei, the signals reach the primary and secondary somatosensory cortex (SI, SII) as a step towards the conscious perception of a noxious stimulus as being painful. Other parts of the cerebral cortex such as the insula and the anterior cingulate cortex (ACC) are reached both in series and in parallel to SI and SII. The distributed processing of nociceptive information is thought to lead to the sensory-discriminative, affective-motivational and cognitive evaluative components of conscious pain perception. Motor and autonomic reactions to noxious stimuli are processed in lower parts of the central nervous system and are mostly independent of conscious pain perception; some of them may still occur after brain death

nociceptive system, leading to ongoing pain. Such pain may, for example, occur in inflammatory conditions and is rationally treated by cooling. The neural basis of primary hyperalgesia to heat stimuli is peripheral sensitization of primary nociceptive afferents by shifts in the temperature sensitivity of vanilloid receptors and related modifications of other ion channels (Cesare et al. 1999).

In secondary hyperalgesia, the mechanical pain threshold may drop in such a way that even gentle stimuli such as movement of cotton wool across the skin is perceived as painful (allodynia). Normal weight bearing on the sole of the feet or contact with clothing then start to act as an adequate stimulus for the nociceptive system, leading to functional deficits by avoidance behavior. Such pain may also occur chronically following lesions of the nervous system (neuropathic pain), and this pain is particularly resistant to current treatment modalities. The neural basis of secondary hyperalgesia to mechanical stimuli is central sensitization of nociceptive neurons in the spinal cord by modifications of the synaptic transmission from A β -fiber mechanoreceptors that normally signal touch and from A-fiber nociceptors (Ziegler et al. 1999).

Central sensitization of the nociceptive system involves the activation of NMDA (N-methyl-D-aspartate) glutamate receptors in the postsynaptic neuron and several additional mechanisms. The intracellular signal pathways are similar to those found for long-term potentiation (LTP) of synaptic efficacy in the hippocampus, which is thought to be related to learning and memory (see *Neural Plasticity and Working Memory, Neural Basis of*). Both LTP and the opposing mechanism long-term depression (LTD) have been observed in slice preparations of the spinal cord using stimulation protocols similar to those that were found to be effective in slice preparations from the hippocampus or neocortex. In the intact organism, the triggering of LTP in the spinal cord is antagonized by the endogenous descending inhibition (Sandkühler 2000). The implications of these mechanisms for the causes of chronic pain are important but not yet fully understood. On the one hand, the intracellular signal pathways of LTP influence gene expression and may thus alter the function of nociceptive neurons for long periods of time. On the other hand, deficiencies in the balance between excitatory and inhibitory influences on the spinal cord may be a decisive factor in pain chronification.

5. Epilogue: Pain and the Brain

If reading the preceding sections have left the impression that the neural basis of actually feeling pain has not been addressed, this impression is correct. It is evident that pain exists only as long as it is being felt by a person. Thus, trying to understand the pain experience as a whole leads into the general mind–

body problem, which is a complex philosophical issue (for a more general account of how personal-level and subpersonal-level descriptions of pain can be combined, see Bieri 1995). This article has intentionally left out the intimate relationship of the subjective pain experience and consciousness. Instead, the preceding sections have described the neural pathways that signal tissue damage and how some of their known properties explain otherwise puzzling phenomena such as the allodynia of neuropathic pain states, where lightly touching the skin may evoke unbearable pain. But how the brain ultimately synthesizes the conscious perception of pain remains a mystery. A few simple examples, however, show that the brain does synthesize this perception:

(a) Blocking the neural pathways between the damaged tissue and the brain (e.g., by a local anesthetic in the dentist's office) creates a situation where there is tissue damage but no pain.

(b) Activation of nociceptive pathways by electrical stimulation within the thalamus may elicit a vivid perception of the pain of a heart attack. In this situation there is pain but no tissue damage.

In other words, a foot cannot hurt by itself, but a brain can perceive a hurting foot. The latter is possible even in the absence of the foot, as observed in phantom limb pain. Pain due to proximal activation of the nociceptive system is called projected pain, because here the normal mechanisms of pain perception are particularly evident: pain sensation is synthesized in the brain, but is then projected into the peripheral receptive field of the active brain areas. Pain due to peripheral activation of nociceptive afferents is called nociceptive pain, but again the pain sensation is synthesized in the brain and projected into the peripheral receptive field, which happens to be the site of tissue damage. This model of pain projection into receptive fields is simplified and does not include the central representation of the body image in brain areas such as the posterior parietal cortex, but this much should be apparent: pain is always in the brain.

Paleodemography: Demographic Aspects

1. Introduction

How long humans lived in the past is a question that has challenged researchers for centuries. Once the dominion of philosophers, theologians, and then historians, physical anthropologists have also struggled to answer this question over the last century. For the physical anthropologist, understanding long-term patterns of the human life span aids in placing observed changes within an evolutionary framework, linking both biological and cultural pressures and adaptations to a changing pattern of life expectancy in populations.

Exploration of this question by physical anthropologists has been primarily in the analysis of skeletal remains recovered archaeologically, and has fallen under the purview of a field developed as a subspecialty of physical anthropology—*paleodemography*.

The early days of paleodemography represented an exploration of modern demographic theory applied to ancient populations and the use of the abridged life table as a tool to aid interpretations of age-at-death profiles from cemetery samples. The 1980s marked a pivotal point for paleodemography. While there had been the occasional critique prior to the 1980s, it was not until 1982 that the great debate over the merits of paleodemography began, sparking several years of controversy within the literature (e.g., Bocquet-Appel and Masset 1982, Buikstra and Konigsberg 1985, Wittwer-Backofen 1987). Subsequent to this period, the two critical issues explored most in paleodemography have been (a) the accuracy of aging techniques, and (b) representativeness of samples.

2. Sources of Data

Paleodemographic studies have focused primarily on the reconstruction of human skeletal samples recovered archaeologically. The basic assumption has been that mortality statistics derived from the skeletal sample are sufficient to make inferences about mor-

tality in the once living population. In conjunction with and sometimes ancillary to skeletal data, archaeological evidence for settlement size and distribution have also been used to estimate population growth or to address more broadly-based questions of population structure in the past. Anthropological demography, of contemporary or recent historic hunter-gatherer and foraging populations, can also provide us with models for prehistoric populations. However, the range of fertility and mortality patterns among populations is so wide and overlapping that ethnographic analogy from subsistence base and mobility is extremely problematic. More recently, evidence from genetic studies has begun to be used to make inferences about long-term evolutionary changes in demographic structure in modern human populations over the past 250,000 years or so.

2.1 Skeletal Remains

The accuracy and reliability of age estimation techniques in particular have been central problems in paleodemography, particularly with respect to underestimation of the ages of older adults. A further issue is the necessary separation of techniques used to estimate age from the skeletal remains of adults vs. children. The latter are based on a various criteria related to known rates of development, whereas the former rely on more variable patterns of rates of development and degeneration of the bony tissues. In addition, differential rates of change between the sexes have made most techniques sex-specific. The scope of this article prevents an in-depth review of such methods, and readers are referred to such classic monographs as Acsádi and Nemeskéri (1970) or Krogman and Iscan (1986) for more detailed descriptions.

2.1.1 Estimation of Age. Determination of age from the adult skeleton can be undertaken using a variety of methods, including both quantitative and qualitative measures of continuous and discrete data. Such methods are referred to as skeletal age-indicator techniques. Adult aging techniques examine both macroscopic and microscopic changes in the morphology and structure of bone. Many macroscopic techniques focus on the pattern of age-related degeneration of bone (e.g., pubic symphysis, auricular surface, sternal end of the fourth rib). Others focus on the remodeling of bone as a biomechanical response to microfractures from everyday wear and tear. The physical anthropologist evaluates multiple criteria for each skeleton and then combines all estimates from each age-indicator method into an overall estimated age range for the individual.

Age estimation from the skeletal remains of children is based on the development of dental and skeletal

tissues, including tooth formation and eruption. Estimation of age in the nonadult is much easier and more accurate than in the adult. While there are fewer techniques than are available for adult age estimation, each has a smaller range of error. Overall, estimation of age from a juvenile is accurate within a range of about plus or minus half a year.

2.1.2 Estimation of Sex. It is recognized widely in the anthropological literature that the pelvis or hipbone is the most reliable part of the skeleton for determination of sex. Both metric and nonmetric or morphological techniques have accuracy rates of better than 95 percent for correct sex, while accuracy rates based on other parts of the skeleton are usually lower. While morphological variables are often preferred because of better preservation in skeletal samples, metric variables are considered by many to be more reliable because of their greater precision.

To the regret of many researchers, however, determination of sex from the skeleton has most often been restricted to those who have survived past adolescence and who then manifest changes in the skeleton reflective of sex. While a variety of studies have investigated traits that might be sexually dimorphic in infants and juveniles, only a few have had sufficient levels of accuracy to warrant their application in osteological analyses. More promising, but still restricted by time and money, is the determination of sex by extracting ancient DNA from the bones or teeth of individuals.

2.2 Archaeological Evidence

While paleodemography has been focused primarily within the realms of skeletal biology, other forms of evidence have also been explored to answer demographic questions. In particular, archaeological demography has often shed light on issues of population structure in the distant past. Estimates of population size and growth have been attempted from settlement data by examining features such the size and area of the living site, number of dwellings, the density and distribution of artifacts and food remains, as well as from ethnohistoric estimates of population size. Even when data are available, estimates of population size must often be made through ethnographic analogy, whereby the relationship between population size and material remains observed in modern or historic groups is imposed on the archaeological site.

2.3 Genetic Evidence

Recent studies of DNA have proposed some interesting hypotheses regarding demographic changes in the past that are of interest when exploring the issue

of long-term trends in human prehistory. In particular, advances in nucleotide divergence theory have provided information on human demographic behavior since patterns of gene differences contain information about the demographic history of a species (Harpending et al. 1998). Genetic data have been used specifically to tackle questions of modern human origins, and the evidence implies human demographic expansion from a population of only several thousand about 250,000 years ago.

3. Representativeness

The representativeness of a skeletal series is a crucial factor in paleodemographic studies. While anthropologists do not expect samples to represent the population in absolute numbers, the fundamental assumption governing the analysis and interpretation of skeletal samples is that the *distribution and pattern of any parameter is the same in the skeletal sample as in the living population that contributed to it*. That is, the pattern observed in the skeletal sample can be used as a proxy for the real pattern within the population. However, a variety of factors serve to bias paleodemographic reconstructions relative to the true demography of the once living population. Biological factors related to the fact that skeletal samples are the nonsurvivor portion of a population, cultural factors related to the burial of the body, environmental factors related to postdepositional processes, and methodological factors related to the excavation and analysis of skeletal samples all serve to potentially bias interpretations.

Until the 1990s few attempts had been made to directly assess the validity of interpretations from paleodemographic reconstructions because of the obvious difficulty in obtaining a skeletal sample that is known to be representative of its larger population. With the more recent, detailed studies of historic cemetery skeletal samples, researchers have begun to test the representativeness of their samples by comparing the mortality data derived from the skeletal sample with the documentary mortality data associated with the cemetery from which the sample was drawn. In most cases, clear differences in demographic parameters estimated from the two sources became apparent. As a result, recognizing and controlling for these biases has become an important part of paleodemographic reconstructions.

4. Reconstructing the Demography of Prehistoric Populations

Traditionally, the statistical tool used by paleodemographers has been the abridged life table. Under the assumption of a stationary population, paleodemography uses mean age at death to estimate

expectation of life at birth. Generally, mean age at death is considered approximately equivalent to the inverse of the birth rate in a population, but is independent of both life expectancy and the death rate. However, when the conditions of a stationary population are not met, this calculation simply represents mean age at death.

Traditionally, the abridged life table has been used by paleodemographers to estimate general mortality patterns with fertility being a by-product. However, several estimators of fertility from mortality profiles have been used. Jackes (1992) has noted that comparisons of the age structures across populations are based on the assumption that there is a relationship between juvenile and adult mortality, and that age-at-death data within very broad age categories will carry some information about the fertility rate of the population. However,

in nonstationary populations, age-at-death distributions are extremely sensitive to changes in fertility but not to changes in mortality Thus, if a population is not stationary—and changing populations never are—small variations in fertility have large effects on its age-at-death distribution, while even quite large modifications of mortality have virtually none (Wood et al. 1992, p. 344).

As a result, many researchers have concluded that the age distribution of skeletal samples provides less information about mortality than it does about fertility, a position supported very early on in the demography literature. In fact, the same fertility and mortality schedules can produce different birth and death rates in populations with different age structures.

4.1 Model Life Tables

In the 1970s demographers expressed concern over the paucity of evidence from which to make statements regarding paleodemographic parameters, forcing investigators to extrapolate from models derived from other sources. Subsequently, model life tables from modern demographic studies formed the basis from which anthropological demographers began to develop model life tables for past populations. Skeletal samples can be compared with a model life table and the fit between model and observed mortality distributions can then be assessed statistically.

The use of model life tables in anthropological demography is twofold. First, it provides a means of assessing or compensating for biased and incomplete data, and second, it allows for the estimation of fertility rates and construction of an initial population at risk. In the early 1970s, Weiss (1973) developed a set of model fertility and mortality schedules derived from ethnographic samples of contemporary hunter-gather societies and prehistoric skeletal samples. Many investigators agree that demographic statistics derived

from contemporary non-Western societies represent an effective means of assessing skeletal age profiles of past populations. However, given the variety of conditions under which many contemporary populations live, it is difficult to be certain that ethnographic analogy will always be appropriate. Further, the application of ethnographic estimators to samples for which related sociocultural information is sparse further compounds the problem.

4.2 Hazard Analysis

Although a potentially powerful tool for paleodemographic analyses, model life table fitting techniques are still subject to potential biases resulting from the use of inappropriate model populations. As an alternative, Gage (1988) proposed the use of a hazard model of age-at-death patterns that can be fitted to survivorship, death rate, and age structure data. As Gage has noted, the Siler model of mammalian mortality is useful for studying human mortality because it reduces the number of variables while maintaining interpretive power. The model for survivorship, which can be fitted to the l_x column in a life table using nonlinear techniques to estimate the parameters, is:

$$l_t = \exp \left\{ -\frac{a_1}{b_1}[1 - \exp(-b_1 t)] \right\} \exp(-a_2 t) \times \exp \left\{ \frac{a_3}{b_3}[1 - \exp(b_3 t)] \right\} \quad (1)$$

where t is age, a_1 is the risk of immature mortality at the moment of birth, b_1 is the rate of decline with age of this risk, a_2 is a constant risk factor, a_3 is the risk of senescent mortality at the moment of birth, and b_3 is the rate of increase in senescent mortality with age (the rate of aging).

The instantaneous death rate or force of mortality at age t of this model is

$$h_t = a_1 e^{-b_1 t} + a_2 + a_3 e^{b_3 t} \quad (2)$$

and the proportion of individuals surviving the immature component is $\exp\{-a_1/b_1\}$ (Gage 1988). This technique provides a method of estimating age-specific mortality and fertility directly from anthropological data, and it can smooth demographic data from a variety of populations without imposing a pre-determined age structure (Gage 1988).

Ultimately, the focus of paleodemography has been to refine methods to improve estimates of age at the individual level in order to get some aggregate estimate of the age structure in the population. More recently, however, researchers have begun to try and estimate

the mortality distribution of a sample directly from the distribution of skeletal age-indicator stages scored. While the difference is subtle, it is important in that such techniques attempt to avoid the broad range of error associated with estimates at the individual level. If one is interested in estimating an individual's age, as in the context of forensic anthropology, then such techniques fall into the category of prediction models. However, if one is interested in shape of mortality or the force of mortality within a population then an alternative theoretical approach is required—one that begins with the overall age structure being estimated, and estimates of individual age being derived secondarily. This apparent paradox in paleodemography was noted by Konigsberg and Frankenberg (1994, p. 96):

Thus, for any single skeleton from an archaeological sample, the posterior probability that the individual is a particular age conditional on the observed indicator is proportional to the prior probability that the individual is that particular age times the probability that an individual that particular age would be in the observed indicator state. However, we do not know this prior probability. If we knew the prior probability of death at particular ages, then we would know the age-at-death distribution, which is precisely what we are trying to estimate. This paradox can be solved by using a common statistical method known as maximum likelihood estimation.

While the precise statistical approach to estimating the mortality structure from skeletal age-indicator data may vary, it is clear that the emerging analytical framework on which paleodemography must move forward begins first with an estimate of the age structure, from which estimates of individual age can subsequently be calculated (cf. Hoppa and Vaupel 2001).

5. Summary

The biological basis for human survival and longevity evolved during the tens of thousands of years of human experience under premodern conditions. A deeper understanding of this basis thus depends on knowledge of mortality and fertility patterns over the long stretch of human existence. Furthermore, deeper understanding of the plasticity of survival and longevity depends on knowledge of how different mortality is today from mortality before the modern era. Paleodemography attempts to address this question by integrating evidence from a variety of sources, but focusing primarily on skeletal, archaeological, and even genetic data. Long-standing interpretations have suggested that the bulk of premodern populations had very short life spans with only a few individuals surviving to middle adulthood. However, new methodological approaches are beginning to readdress this position, and future paleodemographic studies will be able to test this hypothesis more reliably.

Panel Surveys: Uses and Applications

A panel survey makes similar measurements on the same sample units (e.g., individuals, firms) at different points in time (Duncan and Kalton 1987). Panel surveys can be distinguished from: (a) cross-sectional surveys, which take measurements on sample units from a population of interest at a single point in time; and (b) repeated surveys, such as the US General

Social Survey (Davis and Smith 1994), in which similar measurements are made on samples from an equivalent population (e.g., defined by identical geographical boundaries or birth cohorts) at different points of time, but without attempting to ensure that any elements are included in more than one round of data collection.

A widely used alternative term for panel survey is longitudinal survey. However, it is useful to use 'longitudinal' only in the context of longitudinal data; such data may be collected by a panel survey, but they could also come from retrospective reports in a cross-sectional survey.

Most panel surveys follow their sample elements for the duration of the survey. Other panel designs include a rotating panel survey, in which sample elements have a restricted panel life; as they leave the panel, new elements are added. Examples of this are the monthly US Current Population Survey (US Bureau of Labor Statistics 2000a) and the Canadian Labour Force Survey (Statistics Canada 2000), in which the sample at each month is composed of a number of rotation groups, each of which is a self-contained sample from the population of interest. One rotation group drops out and one rotation group enters each month. A split panel survey is a combination of a panel and a repeated survey (Kish 1986).

Panel surveys can differ markedly in the interval between rounds of data collection and the overall length of the survey. On the one hand, a consumer panel in market research may involve weekly contacts with respondents to collect their diary records of purchases. On the other hand, there are long-term panel surveys that may collect data only annually or even less frequently, and these surveys may continue for many years. Examples are the Panel Study of Income Dynamics (PSID), which had been collecting data on US households annually (biannually since 1997) since 1968 (Hill 1992), and the British National Child Development Study, which started in 1958 and has collected data on the sample persons on five occasions in the 33 years to 1991 (Institute of Education 2000).

Some panel surveys are concerned with population subgroups that have experienced the same event during the same time period, such as attending eighth grade in a given year, having been born in a particular week, or having been married during the same period. Since these sample universes are defined as cohorts, such studies are often called cohort studies. Examples include the various cohorts defined by age and sex in the US National Longitudinal Surveys (US Bureau of Labor Statistics 2000b). A limitation of cohort studies is that their results relate formally only to the particular cohorts from which the sample was selected. An extension of the approach is the multiple cohort design, in which several cohorts are followed in similar panel surveys. Thus, the National Longitudinal Surveys have begun three youth cohort panel surveys, in

1968 (males) and 1968 (females), 1979, and 1997, while the Monitoring the Future studies have selected samples of US high school seniors each year, and follow each sample in a panel survey (Monitoring the Future 2000).

Despite their lack of formal population representation, still other panel surveys are valuable because of their detailed interviews and often very long durations. Examples include Elder's (1999) 30-year follow-up of individuals who had attended Oakland, California elementary schools and were enrolled in the Oakland Growth Study when in fifth and sixth grades and Furstenberg's (Furstenberg et al. 1987) 30-year panel study of Baltimore teen mothers who had enrolled in a teen parenting program in 1965.

1. Uses of Panel Surveys

To appreciate the analytic advantages of panel surveys, it is important to realize that the time dimension complicates analyses because: (a) characteristics of population elements may change over time, for instance, an individual may be single one month and married the next; and (b) the population itself may change in composition, with both sample units entering into and exiting from the population.

These complications, especially the first, give rise to a variety of objectives for analysis (Kish 1986, Duncan and Kalton 1987), including:

(a) Estimates of population parameters (e.g., monthly rates of unemployment, public opinion regarding gun control) at distinct time points. The resulting time series of such estimates may be the input for further analysis; see, for example, Smith (1994).

(b) Measurement of net change, defined as change at the aggregate level. An example is the change in the UK unemployment rate between two consecutive months or change in US public opinion regarding gun control before and after a gun-related event.

(c) Measurement of various components of individual change, including: (i) gross change—change at the individual level between two time points (e.g., relating the poverty status of sample members in a given year to their poverty status ten years later); (ii) average change, or trend, for each individual over a period of time, with the average serving to smooth out the effects of isolated perturbations and measurement errors; or (iii) instability for each individual (e.g., the stability of locus of control over 25 consecutive weeks from a sample of elderly in Eizenman et al. 1997).

(d) Aggregation of data for individuals over time. An example is the collection of incomes on an annual basis to relate childhood-long economic well-being to children's developmental outcomes (Blau 1999).

(e) Measuring the frequency, timing, and duration of events occurring within a given time period. Examples are the proportion of persons who were ill in

the past two weeks and the average duration of their illnesses, and the complete fertility histories of post-menopausal women.

If the composition of a population is sufficiently stable to be treated as static for the time period of interest, it may be possible to collect the data required to meet all of these objectives from a single cross-sectional survey conducted at the end of the period. Crucial here is that errors of measurement are acceptably small. Unfortunately, respondents' memories are notoriously inadequate when a substantial time is involved or when the characteristics or events have a low degree of salience for the respondents (Bound et al. 2000). For example, respondents are often unable to recall important events such as unemployment (Mathiowetz and Duncan 1984) or hospitalizations (Cannell et al. 1981) within periods as short as several months, and they cannot reliably recall subjective experiences (Moss and Goldstein 1979). Thus, event data often need to be collected at several points throughout the period.

Repeated surveys can meet some of these analytic goals. Their particular strength is that at each round of data collection they routinely select a sample of the population existing at that time. They thus provide a series of cross-sectional estimates that can be used for objective (a) above. They can also be used to measure overall net change (b). The major limitation of a repeated survey is that it does not yield data to satisfy objectives (c) and (d): since elements are not explicitly included in several rounds, none of the components of individual change can be measured and individual data cannot be aggregated across rounds. Data on the frequency and timing of events in a specified period, as in objective (e), can be collected in a repeated survey, but with the measurement error problems noted above.

The major advantage of a panel survey over a repeated survey is its much greater analytical potential. It enables components of individual change to be measured, objective (c), and also the summation of a variable across time, objective (d). By providing high-quality measurements of the frequency, timing, and duration of events, panel surveys provide data useful for the estimating of event-history models (Tuma and Hannan 1984, Allison 1982, Yamaguchi 1991).

A panel survey can be much more efficient than a repeated survey for measuring net change, objective (b). Let the net change be $y_2 - y_1$, where y_1 and y_2 are the means of the variable of interest at times 1 and 2. Then the variance of the net change is $V(y_2 - y_1) = V(y_1) + V(y_2) - 2\rho[V(y_1)V(y_2)]^{1/2}$ where ρ is the correlation between y_1 and y_2 . In a repeated survey with two independent samples, $\rho = 0$, but in a panel survey ρ is the correlation between an individual's y -values on the two occasions, which is often quite high. In this case, a panel survey will yield a much more precise estimate of net change, objective (b), than will a repeated survey of the same size. On the other hand, as

discussed below, panel nonresponse between times 1 and 2 may result in more bias in the estimation of y_2 in a panel than repeated survey.

A panel survey also permits the collection of a wider range of data on each sampled element than is possible with a repeated survey. The amount of data collected from any one respondent on one occasion is limited by the burden imposed; however, different data can be collected on different rounds of a panel survey, thus providing the possibility of accumulating an extremely wide range of variables for each sampled element. In the US Survey of Income and Program Participation (SIPP), for instance, core data on income and program participation are collected on each round, and additional data on different topics (e.g., health care utilization and financing, pension and retirement issues, housing conditions) are collected on specific rounds only (US Bureau of the Census 2000).

Some long-term panels have important intergenerational components, with data on children and their family contexts taken in early waves and measurements of the adult attainments of the children taken in later waves. Examples include population panels such as the National Longitudinal Survey youth panels, the PSID, the British Household Panel Survey (Institute for Economic and Social Research 2000), the German Socio-Economic Panel, and more specialized data collections such as the Oakland Growth Study (Elder 1999).

2. Problems with Panel Surveys

By attempting repeated interviews with the same sample, panel surveys have problems not found in single or repeated cross-sectional designs, the most important of which is panel nonresponse (initial-wave respondents may not respond in later waves). An additional potential problem with panel surveys is panel conditioning, where responses in a given interviewing round may be conditioned by participation in prior rounds of interviews.

Methods developed to cope with nonresponse bias include minimizing nonresponse in panel surveys and developing statistical adjustments for existing nonresponse. Existing panel surveys typically devote sizeable resources to maintaining high response rates, and sometimes are quite successful. For example, the National Longitudinal Survey of Youth conducted interviews in 1991 with 89 percent of the respondents in its initial, 1979, interview (MaCurdy et al. 1998). Losses in the British National Survey of Health and Development amounted to only 12 percent after 26 years (Atkins et al. 1981).

Incentive payments, respondent reports, persuasion letters, using administrative data for tracing, and collecting extensive contact information (e.g., on friends and relatives not living in the household who would know of address and telephone number

changes) help minimize these problems (Freedman et al. 1980, Clarridge et al. 1978, Call et al. 1982).

As with any survey, sizeable nonresponse in a panel survey gives rise to concerns about nonresponse bias. The situation with the first wave of a panel survey corresponds to that with a cross-sectional survey in that very limited information is available on the nonrespondents. The situation with later wave nonresponse in a panel survey is, however, different: in this case a good deal of information is available about later wave nonrespondents from their responses on earlier waves. The earlier wave information can be used to investigate the possibility of nonresponse bias and to develop imputation and weighting nonresponse adjustments that attempt to reduce the bias (Kalton 1986, Lepkowski 1989).

With regard to conditioning, there is ample evidence from several surveys that initial responses in a panel survey differ substantially from those given in subsequent waves (Bailar 1975, 1979, Ghangurde 1982). In the case of the US Current Population Survey, estimates of unemployment from households entering the sample for the first time are almost 10 percent larger than the average over all eight monthly reporting periods. It is not clear whether there is more response bias in the initial or subsequent waves, because the repeated contact with respondents has ambiguous effects on the quality of the data. The crucial question, as yet unanswered for most phenomena reported in surveys, is whether it is merely the reporting of behavior or the behavior itself that is affected by panel membership.

It may be that data collected in subsequent panel waves is less biased, because repeated contact increases the probability that respondents understand the purposes of the study and are thus increasingly motivated to make the effort necessary to give more accurate answers. On the other hand, there is evidence from a validation study (Traugott and Katosh 1979) that extended participation in a panel study on election behavior not only increased the accuracy of responses on voting behavior but may indeed have increased the amount of voting, so that the behavior of the panel was no longer representative of the behavior of the population at large.

It seems unlikely that panel participation has pervasive behavioral effects, especially when changes in the behavior under investigation require more effort than making a trip to the polls. For example, economic behavior such as work effort, saving, commuting, and home ownership are all unlikely to be affected by responses to occasional interviews. Responses to attitudinal questions may be affected by panel membership if participation stimulates interest in the subject matter of the survey.

The limited membership in a rotating panel acts to reduce the problems of panel conditioning and panel loss in comparison with a nonrotating panel survey, and the continual introduction of new samples helps

to maintain an up-to-date sample of a changing population. Rotating panels are used primarily for the estimation of cross-sectional parameters, objective (a), for the estimation of average values of population parameters across a period of time, objective (b), and for measuring net changes, objective (c). A rotating panel survey will generally provide more precise estimates of point of time and, especially, of change parameters than a repeated survey of the same size. Moreover, a rotating panel survey will sometimes have a cost advantage over a repeated survey. This will occur when it is cheaper to conduct a reinterview than an initial interview, as for instance is the case in the US Current Population Survey where initial interviews must be conducted by personal visit whereas reinterviews on some waves may be conducted by telephone (US Bureau of the Census 1978).

The ability of a rotating panel survey to measure components of individual change, objective (c), and to aggregate data for individuals across time, objective (d), is clearly restricted. Since rotating panels are not intended to serve these objectives, they can be designed to avoid the heavy expense of following movers that occurs with nonrotating panel surveys. Thus, for instance, the Current Population Survey employs dwellings, not households or persons, as the sampled units, so that there is no need to follow households or persons moving between panel waves.

In a split panel survey, the panel survey component can be used to measure components of individual change, objective (c), and to aggregate data for individuals over time, objective (d). Its permanent overlap aids in the estimation of net change, objective (b), between *any* two waves whereas the overlap in a rotating panel survey aids only in the estimation of net change between certain prespecified waves.

Both rotating and split panel survey designs provide samples of new entrants to the population and the capacity to use their panel survey components to check on biases from panel conditioning and respondent losses.

3. The Problem of Changing Populations

The composition of almost every population of interest, whether of individuals, families, firms, or housing units, changes over time. Individuals enter the population when they are born, immigrate, or attain the age or other status that is used to define the population of interest, and depart when they die, emigrate, move into institutions such as jails, nursing homes, or the military, or in some other way lose that status. Families are 'born' when children leave their parents and set up their own independent households or when a divorce or separation breaks up one family into two; they 'die' when all members of the original household die or when two households are merged into a single one through marriage or less formal living

arrangements. Over a survey's time span an element may both enter and leave the population, and may do so more than once, as for instance in the case of a person who has several stays in a nursing home during the course of a survey of the noninstitutionalized population. Comparable changes through construction and demolition, or incorporation, merger, and bankruptcy apply to populations of dwellings and firms.

All surveys over time must address the issues raised by these changes in population composition (Duncan and Kalton 1987). In a repeated survey the cross-sectional parameters of objective (a) relate to the population as it exists at the time the sample is drawn for the particular round of the survey. This procedure reflects both the changing values of the variables under study and the changing population over the time period involved. The estimates are thus average values for a form of average population over time.

Panel studies have adopted a variety of strategies for coping with changing populations. The simplest are panel studies of birth cohorts of individuals in the population, where as many members as possible of the original sample are followed throughout the panel period. In effect, these panels ignore all problems of population composition change except death. Disregarding nonresponse and immigration, these studies represent their respective cohorts as they age, while they gradually cease to represent individuals in the original age range. The National Longitudinal Survey cohorts of Older Men and Mature Women are examples. As discussed above, multiple-cohort panel designs avoid this problem by including in subsequent interviewing waves a sample of new entrants into the population.

Panel designs such as that of the PSID, the British Household Panel Survey, and the European Community Household Panel surveys, contain a mechanism for adding to their samples individuals and families that are 'born' into the population, so they have the potential for maintaining representative samples of nonimmigrant individuals and families throughout their duration. For example, the PSID began with a probability sample of dwellings that, in turn, provides a representative sample of subunits within those dwellings: households, families, subfamilies, transfer program reciprocity units, and individuals. The selection probability of each of these units is identical to the selection probability of the dwelling itself. Other panels composed these subsamples with known selection probabilities through other means. With a properly specified set of rules regarding the definition of units, newly formed subunits of interest (including individuals) enter into the sample with known selection probabilities and reflect corresponding changes that are taking place in the population at large, for example, Hill (1992).

Because they originate from existing panel households, newly formed families and individuals are more

‘clustered’ by family lineage in these designs than in repeated cross-sectional samples; however, the statistical inefficiency of this clustering is heavily outweighed by the analytic advantages of being able to link these newly formed units with information on their families of origin. Thus, information on children setting up independent households can be matched to reliably reported information on their parents, information on ex-spouses can be linked together if the marital split occurred during the panel period, etc. Immigration during the panel period is usually ignored although can be a serious problem for a long-term panel survey confined to a city or a local area, but it is a less serious problem for a national panel survey.

4. Examples of What Panel Surveys Have Found

To help convey the analytic advantages of panel surveys, we list in this section some prominent examples of panel-survey based analyses.

4.1 Poverty and Welfare Dynamics

Trends in annual US poverty rates (i.e., the fraction of the population with family cash incomes below a set of ‘poverty thresholds’ that vary with family size) are tracked through cross-sectional estimates based on the Current Population Survey. Net change from one year to the next in these rates rarely amount to as much as a single percentage point (US Bureau of the Census 1999), producing perceptions that ‘the poor’ are an ever-present and little-changing group.

By applying event history methods to the time series of annual poverty measurements for PSID sample members, Bane and Ellwood (1986) characterized the nature and determinants of poverty experiences by the length of their ‘spells’ (i.e., continuous periods of poverty). They find that a clear majority (60 percent) of families who first begin a poverty experience do so for short (i.e., spells of 1 or 2 years) periods of time. On the other hand, a subset of poor families (14 percent) have longer-run (8 or more years) spells, and the remaining one-quarter (26 percent) have medium-length (3–7 years) spells. Thus, there is no single ‘correct’ characterization of poverty—transitory or persistent—since poverty experiences are a mixture of transitory and long-term.

By combining individual spells into simulated lifetime histories, Bane and Ellwood (1994) provide estimates of the likely total number of years of receipt for families just starting to receive cash assistance from the US Aid to Families With Dependent Children program. They find a roughly even distribution of first-time welfare recipients across the three time intervals; roughly one-third (36 percent) have very short welfare experiences, a third (35 percent) medium-length experiences, and the final third (29 percent)

long-term receipt. With welfare, as with poverty, heterogeneity is a key feature, with many families using AFDC as short-term insurance, but a substantial fraction of recipients receiving long-term assistance.

4.2 Intergenerational Transmission of Economic Status

Correlations in earning between fathers and sons is sometimes treated as a useful measure of intergenerational (im)mobility. Solon (1992) argues that there are two important sources of bias in attempts to estimate such correlations: single year proxies for long-run economic status contain transitory fluctuations that, under plausible assumptions, impart a downward bias to the correlation estimates, and samples used in previous studies (e.g., Mormon brothers, white twins who served in the armed forces) tend to be peculiarly homogeneous, also resulting under plausible assumptions in a downward bias to estimates based on homogeneous than population-based samples.

Data from both the NLSY (in Zimmerman 1992) and PSID (in Solon 1992) have been used to gauge the likely biases. For example, Solon et al. (1992) find that increasing the measurement interval for economic status from one to several years causes their estimate of the father-son earning correlation to jump from 0.25, a number consistent with past studies based on single-year earnings measurement and homogeneous samples, to 0.45. Thus, intergenerational economic mobility appears to be substantially lower than had been depicted in studies based on homogeneous samples and single-year measures of income or earnings.

The more specialized panel studies of Elder and Furstenberg provide much more detail on the process of intergenerational mobility. Using 30-year follow-up data on the Oakland Growth Study cohorts, Elder (1999) found in these children of the Great Depression strong associations among economic hardship, parental psychological well-being, and adolescent well-being in intact families.

Fathers who experienced job loss and economic deprivation were more distressed psychologically and prone to explosive, rejecting, and punitive parenting. Preschool-age children in these families, especially boys, were more likely to exhibit problem behaviors, while adolescent girls were more likely to have lower feelings of self-adequacy and to be less goal-oriented. Elder (1999) speculated that the gender and age differences reflected different experiences in families during the deprived times. Adolescent boys reacted to family economic hardship by looking for economic opportunities outside of the home. This time spent taking on responsibility in extra-family contexts reduced the time they spent with their families and may have provided a buffer to the effects of negative family

interactions. Younger children and girls were unable to seek such extra-familial opportunities as readily and therefore did not have access to buffering opportunities.

Furstenberg et al. (1987) take a detailed look at intra- and intergenerational mobility in a panel study of a poor teen mothers participating in a program in a Baltimore hospital. Their 20-year follow-up revealed considerably diversity in the mothers' economic and demographic statuses, with most self-supporting but very few stably married. Most (60 percent) of the daughters of the teen mothers had not themselves become teen mothers and three-quarters enjoyed at least a modest degree of economic success. In contrast, fewer than half of the sons of the teen mothers had attained successful economic trajectories.

4.3 Unemployment and Labor Turnover

Both unemployment and job turnover are most naturally thought about in a 'spells' framework: how long does a spell of unemployment last before employment recommences? How long does a spell of employment with one firm last before the worker leaves to take (or look for) alternative employment? Given the inherently longitudinal nature of these processes, it is not surprising that panel surveys have played an important role in research on these topics. While much research on this topic has used administrative records, a panel survey has the advantages of including those who do not receive unemployment benefits, for comparison to recipients, and it continues observing spells after benefits have been exhausted (i.e., it measures total spells, not just insured spells), so one can observe changes in job-finding rates after benefits are exhausted.

An example is Katz and Meyer's (1990) study of the impact of unemployment insurance on unemployment duration. Katz and Meyer find that probability of recall declines as the duration of a spell increases, for both recipients and nonrecipients. New-job rates, however, are upward-sloping for recipients but relatively flat for nonrecipients. Moreover, there are spikes in both the recall and new-job hazard rates around 26 and 39 weeks (when benefits were typically exhausted in their sample period) for recipients but not for nonrecipients. Thus, not only is there evidence that the approaching end of benefits conditions recipients' job finding, but it also conditions firms' recall policies.

4.4 Antecedents of Life Events

There is great interest in understanding the consequences of important life events such as divorce, widowhood, unemployment, and retirement. Cross-sectional data provide comparisons of, for example, the living standards and labor supply of divorced

women and 'otherwise similar' married women, or the health of unemployed or widowed men with 'otherwise similar' employed or married men. But panel surveys provide valuable post- and, interestingly, pre-event data on the same individuals.

For example, Johnson and Skinner (1986) use data from the PSID to examine work hours of women between seven years before and four years after divorce or separation. Consistent with other research, they find that the average work hours of these women rose by half (from 1024 to 1551 hours) between one year before and four years after the divorce or separation. But Johnson and Skinner (1986) also found a big jump (from 744 to 1024 hours) over the six-year period *prior* to the divorce or separation.

Zick and Smith (1991) analyze the economic antecedents and consequences of widowhood by comparing family-income trajectories of a control group of intact couples with widowed women and men between five years before and five years after the spouse's death. They too find differences prior to the event, with income changes over the five years *prior* to the death accounting for about one-quarter of the control-widow difference at $t+5$ and for fully half of the control-widower difference. A clear message from both of these analyses is that impending life events such as divorce and death produce measurable economic and social changes long before the events actually occur. An implication is that fairly long panels are needed to capture the complete dynamic.

G. J. Duncan

Panic Disorder

Panic disorder (PD) is an anxiety disorder associated with recurrent, unexpected panic attacks, characterized by sudden surges of physical arousal and fear. In addition, most individuals with PD develop agoraphobia to varying degrees. Agoraphobia is a fear of situations in which escape might be difficult or embarrassing, or in which help might be unavailable in the event of a panic attack.

The terms 'PD' and 'panic attack' first appeared in the diagnostic nomenclature with the publication of the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III, American Psychiatric Association 1980). Initially, panic attacks were seen primarily as a feature of agoraphobia. In DSM-III, agoraphobia could be diagnosed with or without panic attacks, and individuals who experienced unexpected panic attacks in the absence of agoraphobia received a diagnosis of PD without agoraphobia.

More recently (e.g., DSM-IV, American Psychiatric Association 1994), the relationship between panic

disorder and agoraphobia has reversed, such that PD is seen as the primary problem, and agoraphobia is viewed as a complication of PD. The disorder 'agoraphobia with panic attacks' has essentially been replaced with 'panic disorder with agoraphobia' to reflect the fact that, in clinical groups, agoraphobia tends to develop as a response to having unexpected panic attacks, rather than the other way around (Craske and Barlow 1988).

1. Definitions and Description

1.1 Panic Attack

DSM-IV (American Psychiatric Association 1994) defines a panic attack as a period of intense fear or discomfort that begins quickly and peaks in ten minutes or less. A panic attack must also be accompanied by at least four out of a list of 13 symptoms, which includes eleven physical sensations (i.e., racing or pounding heart, sweating, trembling, shortness of breath, choking feelings, chest discomfort, nausea, dizziness, feelings of unreality or depersonalization, numbness or tingling sensations, hot flashes or chills) and two cognitive symptoms (i.e., fear of losing control or going crazy, fear of dying).

Panic attacks are common in the general population and are also associated with a broad range of psychological problems. For example, people who experience intense worry may have a panic attack in response to a particular worrisome thought. Individuals who are fearful of a specific situation (e.g., seeing a spider, being in a high place) may experience panic attacks when confronted with these situations. Panic attacks may also occur in the absence of any obvious cue or trigger. In fact, the hallmark symptom of PD is the presence of panic attacks that occur out of the blue.

1.2 Panic Disorder

People who suffer from PD experience recurrent unexpected or uncued panic attacks. In addition, they must experience, for at least one month, one or more of the following: (a) persistent worry about having more panic attacks; (b) frequent worry about the implications of consequences of the attacks (e.g., that an attack will lead to a heart attack, death, fainting, diarrhea, vomiting, embarrassment, or some other catastrophe); or (c) a significant change in behavior related to the attacks (e.g., avoidance of certain situations or activities). Finally, before assigning a diagnosis of PD, the clinician must establish that the panic attacks are not directly related to another psychological problem (e.g., a specific phobia), a medical condition (e.g., hyperthyroidism), or use of a substance (e.g., cocaine, caffeine). Panic disorder may be diagnosed with or without agoraphobia.

1.3 Agoraphobia

A significant proportion of individuals suffering from PD develop agoraphobia, a fear of situations in which escape might be difficult, or in which help might not be available in the event of a panic attack (American Psychiatric Association 1994). Typical situations that are often avoided by people with agoraphobia include crowded places (e.g., concerts, movies, shopping malls), driving, traveling, public transportation, flying, enclosed places, and meetings. For some individuals with agoraphobia, it is the distance from home, rather than the situation itself, that determines the level of fear and avoidance. For example, driving may be difficult, but only if the car ventures more than a few kilometers from home. For many people who suffer from agoraphobia, entering feared situations is easier if accompanied by a safe person, such as a spouse, family member, or close friend. In extreme cases, agoraphobia may be associated with a complete inability to leave the home, even when accompanied.

In addition to the obvious avoidance associated with agoraphobia, individuals with PD often engage in more subtle forms of avoidance. For example, a person might see a movie in a theater, but only if sitting in an aisle seat, near the exit. Or an individual might agree to ride a bus only while engaging in distracting behaviors such as reading or listening to a portable radio. Individuals with PD may also carry objects with them to feel safer, including medication, extra money in case of an emergency, or a portable telephone. Finally, they may engage in overprotective behaviors such as frequently checking their heart rate or blood pressure.

2. Epidemiology, Onset, and Demographics

Antony and Swinson (2000) reviewed the literature concerning age of onset and risk factors for developing PD. PD begins on average when a person is in his or her mid- to late-20s, although onset can occur any time between childhood and late in life. Risk factors include a period of life stress preceding the first attack, being female, a history of childhood separation anxiety, and a history of either substance abuse or dependence (Antony and Swinson 2000).

In the National Comorbidity Survey (a study of over 8,000 Americans in the general population), 3.5 percent of individuals reported symptoms meeting criteria for panic disorder with or without agoraphobia at some time in their life (Kessler et al. 1994). The lifetime prevalence of agoraphobia was 6.7 percent, with about two-thirds of agoraphobics having no prior history of panic attacks or panic disorder (Magee et al. 1996). This finding is in direct contrast to studies based on individuals in clinical settings, where agoraphobia almost never occurs separately from panic disorder (Pollard et al. 1989).

People with PD report impairment across a broad range of life domains including work, recreation, and social functioning (Antony et al. 1998). Furthermore, PD is associated with enormous costs to sufferers and to society, in the form of increased health-care utilization, lost wages, and time off work (e.g., Greenberg et al. 1999). PD is also associated with a higher risk of developing other psychological problems, including other anxiety disorders, depression, certain personality disorders (e.g., dependent, avoidant), and substance-use disorders (for a review, see Antony and Swinson 2000).

3. *Biological Approaches to Understanding Panic Disorder*

3.1 *Biological Models of Panic Disorder*

Most biological approaches to understanding PD have assumed a dysfunction in one or more neurotransmitter systems, including norepinephrine (NE), serotonin (5-HT), and cholecystokinin (CCK). In addition, theorists have hypothesized that genetic and neuroanatomical factors are also involved in the development of PD.

Perhaps the most influential biological model of PD in recent years has been Donald Klein's suffocation alarm model (Klein 1993), which proposes that panic attacks are caused by a pathological misfiring of the suffocation alarm system. According to Klein, humans are equipped with two types of alarm reactions. The first is controlled by the hypothalamic-pituitary-adrenal (HPA) axis and is responsible for dealing with real or perceived emergency situations. It is this alarm system that is activated when an individual is confronted with a feared object or situation.

The second alarm system is the suffocation alarm system, which is mediated by an area of the brain known as the *locus ceruleus*. This alarm system is triggered by increased levels of carbon dioxide in the blood, a sign that individuals might be in a small enclosed area, forced to breathe their own exhaled air, which is rich in carbon dioxide. Klein hypothesized that unexpected panic attacks occur when an individual has a pathologically lowered threshold for the activation of the suffocation alarm system. Presumably, the brains of such individuals are prone to mistakenly conclude that there is not enough air to breathe. As reviewed elsewhere (Antony and Swinson 2000), evidence regarding Klein's model has been mixed.

3.2 *Evidence Regarding Biological Approaches to Panic*

Despite inconsistent evidence for Klein's model, there are many studies supporting the view that biological

processes are involved in the pathophysiology of PD. PD tends to run in families and evidence from twin studies suggests that genetics plays a significant role in the transmission of PD across generations (e.g., Kendler et al. 1992). Findings from brain-imaging studies suggest that the temporal areas of the brain (particularly the right hippocampal region) are involved in the experience of panic attacks and fear (for a review, see Antony and Swinson 2000).

Evidence regarding the role of neurotransmitters in PD have included studies of altered receptor functioning, levels of particular neurotransmitters and related metabolites, and responses to substances that are known to cause changes in neurotransmitter levels. Among neurotransmitters, NE is the one most often implicated in PD and agoraphobia (Sullivan et al. 1999), although other neurotransmitter systems, such as 5-HT (Bell and Nutt 1998) and CCK (Bradwejn 1995) may also play a role. There is evidence that levels of NE metabolites predict panic-related symptoms (Garvey et al. 1990) and of altered NE receptor sensitivity in people suffering from PD (Nutt 1989). In addition, drugs that block the reuptake of NE appear to be effective for preventing panic attacks (Mavissakalian and Perel 1989).

Finally, a large number of studies have shown that certain substances that affect the NE system are more likely to trigger panic attacks in people with PD than in various comparison groups. Infusions of sodium lactate, carbon-dioxide inhalation, and yohimbine injections have all been shown to trigger panic attacks. However, it should be noted that psychological factors such as perceived control over the procedure and the presence of a safe person can influence whether an individual will experience a panic attack following exposure to these substances (for a review of panic induction studies, see Antony and Swinson 2000).

4. *Psychological Approaches to Understanding Panic Disorder*

4.1 *Psychological Models of Panic Disorder*

Attempts to explain PD using a psychological framework have come from a broad range of theoretical perspectives, including cognitive theory, learning theory, and psychodynamic theory. However, the most influential of these models have been those developed by cognitive and behavioral theorists such as David M. Clark (Clark 1986) and David H. Barlow (Barlow 1988).

From a cognitive behavioral perspective, PD is viewed as being maintained by a fear of benign physical sensations. For example, according to David Clark's cognitive model of PD, panic attacks stem from a tendency to misinterpret normal physical sensations (e.g., racing heart, dizziness) as indicating

some immediate danger. As a result of interpreting these sensations as being threatening, the symptoms escalate, leading to further catastrophic interpretations and predictions. Very quickly, the symptoms spiral into a full-blown panic attack, seemingly out of the blue. Clark and other cognitive theorists acknowledge that biological factors may also contribute to the experience of panic. The sensations that initially start the panic cycle may be caused by caffeine, intense emotions, exercise, hormonal changes, fatigue, hunger, hyperventilation, attention to bodily feelings, or other factors. Consistent with the cognitive behavioral view, 70 percent of individuals with PD report that their panic attacks are triggered by a physical sensation (Breitholtz et al. 1998).

4.2 Evidence Regarding Psychological Approaches to Panic

A number of studies have confirmed that people with PD are fearful of the physical sensations associated with panic attacks, compared to people without PD and people with other anxiety disorders (e.g., Taylor et al. 1992). In addition, researchers have demonstrated that people with PD are more likely than others to interpret ambiguous physical sensations as a sign of some impending physical or mental disaster and to believe these thoughts quite strongly (Clark et al. 1997).

Numerous studies have also found that people with PD have information-processing biases that are consistent with their fears. For example, a number of studies have found that PD is associated with a heightened ability mentally to track physical sensations such as heart rate (e.g., van der Does et al. 2000). In addition, results from studies of attention and memory have also been consistent with psychological models of PD. Compared to people without PD, individuals with PD attend more to threat-related information (e.g., McNally et al. 1994) and are more likely than nonanxious individuals to show threat-related biases in memory (e.g., Amir et al. 1996).

In summary, individuals with PD are typically more fearful of and more vigilant for panic-related sensations, compared to people without PD. PD is also associated with a tendency to hold fearful beliefs about panic-related sensations, and to show biases in attention and memory for threat-related information.

5. Treatment of Panic Disorder

In 1998, the American Psychiatric Association published practice guidelines for the treatment of PD. In addition to discussing important issues in the assessment and treatment of this condition, the guidelines reviewed the main approaches that have been shown to be useful for treating PD. Essentially, these

approaches include treatment with medications, and treatment with cognitive-behavior therapy (CBT). A review of studies on the relative and combined effects of these interventions is available elsewhere (e.g., Antony and Swinson 2000). A brief summary of the major findings is provided below.

5.1 Medication Treatments

A large number of controlled clinical trials have established that certain medications are useful for treating PD with and without agoraphobia. The tricyclic antidepressant imipramine is the most extensively studied medication that has been shown to be effective for blocking panic attacks (e.g., Mavissakalian and Perel 1989). More recently, controlled trials have established that the selective serotonin reuptake inhibitors or SSRIs (e.g., fluoxetine, fluvoxamine, sertraline, paroxetine, citalopram) are also useful for treating PD; in fact, the SSRIs are now often considered to be the pharmacological treatment of choice for this condition (for a review, see Antony and Swinson 2000).

Finally, controlled trials have found a number of other antidepressants to be useful, including venlafaxine (a new antidepressant) (Pollack et al. 1996) and phenelzine (a monoamine oxidase inhibitor or MAOI) (Buigues and Vallejo 1987). Studies with high-potency benzodiazepine anxiolytics such as alprazolam have consistently shown these medications to be effective as well (e.g., Ballenger et al. 1988).

Despite the long list of medication options for treating PD, there is little consistent evidence that any one of these medications is more effective than the others. Choosing among medications for a particular individual usually depends on factors such as potential side effects, possible problems during discontinuation (e.g., rebound anxiety), the patient's previous history of treatment response, the cost of the drug, and potential interactions with other medications, substances, or medical illnesses.

5.2 Cognitive-behavior Therapy

Cognitive-behavior therapy for PD includes four main types of strategies: (a) exposure to feared situations such as crowds, public transportation, and being away from home alone (i.e., *in vivo* exposure); (b) exposure to exercises that trigger feared sensations (e.g., overbreathing or spinning to induce feelings of dizziness); (c) cognitive therapy (i.e., systematically considering evidence that contradicts fearful thinking); and (d) relaxation-based strategies (e.g., learning to slow down one's breathing). Most of the time, treatment includes various combinations of these strategies.

A number of comprehensive reviews on CBT for PD have been published (e.g., Antony and Swinson 2000,

Barlow and Brown 1996, McNally 1994). Generally, there is little evidence that it is necessary to include all four treatment components to achieve maximum results. *In vivo* exposure to feared situations appears to be particularly important for treating individuals who are agoraphobic. In addition, relaxation-based strategies are thought to be less important than the exposure-based and cognitive techniques.

Although CBT for PD lasts 10 to 15 sessions, a number of recent studies suggest that gains can be made relatively quickly, with a minimal investment of therapist time. For example, telephone-administered CBT has been used to treat people who do not have easy access to a therapist (Swinson et al. 1995) and a single session of CBT has been shown to prevent the onset of PD in a significant percentage of individuals who present to hospital emergency rooms with a panic attack (Swinson et al. 1992). Finally, a number of studies have found that brief CBT lasting only five sessions (Clark et al. 1999) and CBT delivered in a self-help format (e.g., Hecker et al. 1996) are both useful for helping people to overcome PD (see *Cognitive and Interpersonal Therapy: Psychiatric Aspects*).

5.3 Combination Treatments

Studies comparing medications, CBT, and their combinations have yielded inconsistent results (Antony and Swinson 2000). However, averaging across a large number of studies, it is reasonable to conclude that both medications and CBT are effective for treating PD and there is no clear evidence favoring either antidepressants, high-potency benzodiazepines, CBT, or their combinations for treating panic attacks (e.g., Bakker et al. 1998, van Balkom et al. 1997). However, the combination of antidepressants and *in vivo* exposure appears to be particularly useful for treating agoraphobic avoidance (van Balkom et al. 1997).

It should be noted that most studies on the treatment of PD have focused primarily on the short-term effects of treatment over a period of only two to three months. Few studies have examined the relative effects of medications and CBT after treatment is discontinued. Exceptions include three studies comparing the relative and combined effectiveness of CBT with either imipramine (Barlow et al. 2000), alprazolam (Marks et al. 1993), or fluvoxamine (Sharp et al. 1996). In all three studies, individuals who received CBT (alone or in combination with medication) were more likely to maintain their gains over the long term than individuals who received only medication or placebo treatment.

Taken together, the literature on treating PD suggests that CBT and pharmacotherapy are both effective treatments in the short term. However, there is evidence that CBT is a more effective treatment for ensuring that gains are maintained over the long term.

Panic, Sociology of

The term 'panic' is widely used in everyday speech as well as in the literature of different professional areas and scientific disciplines. This leads to a very wide diversity in the attribution of both the characteristics of, and the conditions that generate, the phenomenon. However, this article confines itself primarily to how sociologists view 'panic.' Thus, it does not consider the substantial but circumscribed literature in economics that focuses solely on 'financial panics,' or another set in psychiatry that deals with 'panic states' from a mental health viewpoint. Although a few sociologists have looked at the first phenomenon under the general rubric of panic, the second has never been of any concern to them.

The focus on sociology is justified for several reasons. From the very origins of the field, sociologists have used the term as part of their professional vocabulary. The first introductory sociology textbook states that 'panic is the crowd in dissolution' (Park and Burgess 1924, p. 876) because it is the opposite of the crowd in the sense of not having any psychological unity. In particular, panic has always been considered part of the subject matter of the sociological specialization of collective behavior, which deals with nontraditional and newly emergent forms of social action (see Sociology of Collective Behavior). Most US textbooks and extended theoretical treatises on collective behavior discuss panic (Miller 1985) with some giving

extensive attention to the phenomenon. Furthermore, such empirical studies of panic as have been undertaken have been mostly by sociologists studying human and group behavior in natural and technological disasters (see *Disasters, Sociology of*). Even psychologists, who next to sociologists have been most interested in panic, primarily cite empirical and theoretical sociological sources (Schultz 1964).

1. Past Approaches

The first extended and systematic treatment of panic by a sociologist is a chapter by LaPiere (1938) in a little-known book on collective behavior. He sees panic as dysfunctional escape behavior generated by fortuitous, ever-varying circumstances, but involving impending danger. Panic is never formally defined except as the antithesis of regimental behavior, which is preplanned collective action for dealing with crises, such as fire drills in schools. Instead what constitutes panic is illustrated by presentations of anecdotal examples from stories of disaster behavior in journalistic and popular sources. While his vague formulations and use of popular sources are typical, LaPiere differs from many later writers in three major ways. He does not generally deal with any covert emotional or feeling state associated with the behavior, and he avoids use of the term 'irrational.' In addition, he distinguishes between collective and individual panic, which is at variance with most treatments, which imply that panic necessarily involves a multiplicity of participants.

As just implied, there is little consensus, historically or currently, on the use of the term. Nevertheless, most discussions about the nature of panic can be grouped into one of two categories. The oldest view, coming out of everyday speech, primarily equates panic with extreme and groundless fear. This is clearly related to the linguistic origins of the word which is derived from the Greek god Pan, who supposedly was able to generate sudden and overwhelming fear in the absence of any actual threat. For many writers taking this position, being seized by such a fear can lead to other irrational reactions although the essence of panic is the emotional manifestation, and not what this might otherwise affect.

Another view visualizes panic as manifesting itself primarily as flight behavior. In this conception, the essence of panic is the overt behavior that is marked by the setting aside of everyday social norms, even the strongest, such as parents abandoning their young children when trying to save themselves in a life-threatening crisis. Often implicit, there is the assumption in this view that such flight behavior will occur only if there is a perception that there is a possibility of escaping the threat. Disaster researchers in particular have emphasized that hope of escape rather than hopelessness is what is involved. People who perceived

themselves as totally trapped, such as in sunken submarines or collapsed coal mines, do not panic because they see no way of getting away from the threat.

Of course it is possible to put the two general formulations together. Smelser (1963, p. 131) defines panic as 'collective flight based on a hysterical belief,' which allows him to talk both about overt escape behavior and the selling behavior of investors in financial panics. But others have noted that the relationship between a terror state and rout behavior is not necessarily a direct one, given that whatever the emotion, it need not inevitably lead to flight of any kind. Apart from agreeing that panic participants are very afraid of some perceived threat, there is little agreement otherwise among students of the phenomenon on the relationship of the emotional state involved to what other, if any, behaviors will be manifested.

2. Current Issues

Apart from differences about the nature of panic, many discussions of panic focus on two other major themes. One such theme, and a very prominent one, assumes that panic behavior is 'irrational' (cf Le Bon [1895] 1960). This is often contrasted with the assumed rationality of most other behavior, where the means-ends relationships are in balance or where the end result is a positive one. This conception has come under sharp criticism, especially from those who have done empirical studies of the behavior of people caught in disasters and fire situations (Quarantelli 1981). These researchers note that when the behavior on such occasions is looked at from the perspective of the social actors involved, the behavior is very meaningful and far from most conceptions of irrationality (Johnson 1985). The argument is that nothing is gained by characterizing the behavior as irrational or along any similar dimension (Wenger 1980). However, it is still very common and typical for social science textbooks that discuss panic to characterize it as irrational.

A second major division among scholars is between those who argue that panic behavior is very contagious, and that human beings are easily swept up into the behavior, and those who strongly disagree with such a conception. Many of the early discussions of panic clearly assume that the participants are overwhelmed by the fearful emotion of others, and will trample over others in their path. In contrast are those researchers who take the position that whatever panic behavior is, it results from meaningful social interaction among the participants. They note that even in those rare cases of extreme instances of panic flight, very few spectators ever get caught up in the behavior.

Several specific studies have particularly influenced all of the previous arguments. One is a study by Cantril (1940) on reactions in the USA to a nationally broadcast radio show supposedly reporting as actual fact an alien invasion from Mars. The study takes the view that those who panicked upon hearing the broadcast lacked 'critical ability.' The behavior was seen as irrational. While even to this day this study is cited as scientific support for this view of panic, the research has come under sharp critical scrutiny. Analysts have noted that even taking the data reported at face value, only a small fraction (12 percent) of the radio audience ever gave even any remote credence to the idea that the broadcast was an actual news story. And the accounts of flight behavior as well as other illogical and bizarre actions reported in the book give the mistaken idea that they were obtained in the survey study done. Actually, they are taken almost unacknowledged from journalistic accounts of the time which reported that supposedly numerous people fled wildly to get away from the alien invaders. A close scrutiny of the actual news report that appeared found that most of them were sensationalized anecdotal stories that these days are typically reported in the tabloid press.

The last point is particularly important because much later Rosengren and his colleagues (1978) studied in a very systematic manner a roughly similar radio show. A Swedish radio station broadcast a fictitious news program about a nuclear plant accident that had created radioactive clouds drifting in southern Sweden. Within an hour, other media were broadcasting reports about widespread panic reactions in the population, with the print media later reporting panic reactions of various kinds on a large scale including escape flight. However, the systematic survey study found less than 10 percent of the audience gave any credence to the broadcast, with less than 1 percent showing any behavioral reaction, and no one who had engaged in flight behavior. The research showed that the supposed panic reaction of the population was almost exclusively a mass media creation. There is very little found by this research that would be supportive of any of the formulations about panic advanced to that time by social scientists.

More recently, Johnson (1988) did intensive studies of persons caught in potential panic-provoking situations such as a fire in a night club and a stampede during a rock music concert, where 160 and 11 persons respectively died. The findings are unambiguous. The great majority of involved persons did not engage in animal-like behavior, contrary to what many early writers on panic suggest occurs. Instead of ruthless competition, the social order did not break down, with cooperative rather than selfish behavior predominating. Contrary to notions of irrationality, there was much evidence for rational responses in the face of the crisis. While strong emotions were experienced, these did not lead to maladaptive behavior. These findings

reinforced the ever-growing viewpoint among many researchers who have studied what seem potential panic situations, that prosocial rather than antisocial behavior predominates even in such contexts.

3. *Future Questions*

Two additional and fundamental but unresolved questions regarding the concept of panic are surfacing. Most scholars seem to agree that whatever 'panic' might mean, the phenomenon is statistically quite rare, usually involves only a handful of persons, and is of short duration. Some researchers have observed that it is very difficult to find clear-cut cases of actual panic in natural and technological disasters (and that they are also extremely rare in the other arena in which they supposedly occur, that is among soldiers in battles during wars). But the term continues to be widely used and persists, despite, the lack of empirical evidence that it happens on any significant scale; it also continues as noted by students of popular culture to be the staple of disaster movies and novels.

Wolfenstein (1957) explicitly questioned why, despite what the research evidence showed, the idea of 'panic' captures the popular imagination and continues to be evoked by scholars of human behavior. Using a psychoanalytical framework, she suggests that the fascination with the term is a psychological fantasy actually useful and functional in a variety of ways for coping with personal crises. Some disaster scholars have thought that a more sociological approach might parallel what Durkheim, a major figure in the origins of sociology, said about crime. If it did not exist, it would be necessary for human societies to create crime, at least symbolically, so as to emphasize the fact that human beings generally adhere to social norms. So perhaps the idea of the possibility of panic is necessary in society to highlight the fact that human beings in contrast react remarkably well in most stressful situations and that the social bonds between and among people usually hold. Supporting this view, as disaster researchers have noted, the mass media in reporting the *absence* of panic are behaving as if the normal expectation is that panic will occur. Whatever the merit of the parallel to crime, clearly there is a need to explain the huge discrepancy between the actual frequency of panic in any sense of the term, and the exaggerated interest in and widespread use of the word, not only in popular culture but also especially among social scientists who have not researched the phenomena.

A second basic question is whether there is still any scientific justification for the continuing use of the concept in any technical sense. Increasingly, students of the phenomenon have questioned if the term 'panic' ought to be continued to be used by students of collective behavior (Mawson 1980, Sime 1981). The logic of the argument is that such behavior as is attempted to be captured under that label can better be

dealt with by using other concepts. In other words, what is often currently described and analyzed as panic behavior can be characterized and explained by other terms. Those taking this view argue that because a word has widespread popular currency, and has been unthinkingly imported into a scientific field, this should not be seen as necessarily giving the term any legitimacy. From this perspective, it is possible that the concept of panic within collective behavior in sociology may disappear as a technical term in the future.

Paradigms in the Social Sciences

How is one to explain the diffusion of the concept of 'paradigm,' a word of Greek origin used by some philosophers during the eighteenth century, and which, in the writings of some contemporary scholars, has a pedantic tone? One of the reasons may be the fact that it raises what is, in the history of science, a fundamental question: is scientific progress achieved mostly by steady accretion or mostly by abrupt jumps? This concept was devised by Thomas Kuhn in a particular context, and the circumstances of its formulation poses directly the question to be treated here: Are there paradigms in the social sciences?

1. A Polysemic Concept

Thomas Kuhn explains in the preface to *The Structure of Scientific Revolutions* (Kuhn 1970) that it was during a stay at Palo Alto Center for Advanced Studies, in the company of social scientists, that he was led to formulate the concept of paradigm with the aim of making clear the essential difference between natural sciences and the social sciences. The reason given by Kuhn was the absence of a theoretical consensus in any discipline of social sciences.

I was struck by the number and extent of overt disagreement between social scientists about the nature of scientific problems and methods... Controversies over fundamentals seem endemic among, say psychologists or sociologists... Attempting to discover the source of that difference led me to recognize the role in scientific research of what I have since called paradigms (Kuhn 1970, p. VIII).

For him, the use of the word paradigm in the social sciences is not justified.

As a preliminary it should be noted that many scholars have formulated doubts about the reality of paradigms even in the natural sciences—an issue that cannot be discussed here. Kuhn himself has in the postscript to the second edition of his book reformulated the concept of paradigm, by disentangling this concept from the notion of scientific community, and by admitting that he has used the term in two different senses. On one hand, paradigm stands for a constellation of beliefs, values, techniques and so on shared by the members of a given community; on the other, it denotes a concrete puzzle-solution. He labeled the first meaning 'disciplinary matrix': 'disciplinary, because it refers to the common possession of

the practitioners of a particular discipline; matrix, because it is composed of ordered elements of various sorts' (Kuhn 1970, p. 182). Kuhn makes a distinction between paradigms in the large sense, the disciplinary matrix, and small paradigms called 'exemplars.' This distinction is considered unclear by several sociologists of science.

In the revised version of Kuhn's thesis

any period of scientific development is marked by a large number of overlapping and interpenetrating paradigms, which do not replace each other immediately and do not spring up full-borne, but instead emerge in a long process of intellectual competition... These concessions dilute Kuhn's original message, and in its final version the argument is difficult to distinguish from the average historian's account of the history of science (Blaug 1976, p. 154).

Among the sociologists of science, very few have asked if the concept of paradigm is, or not, applicable to social sciences. Harriet Zuckerman in her substantial *Sociology of Science* (Zuckerman 1988) does not dedicate a single line to this issue, nor do Merton, Price, Collins, Lakatos, or Mullins.

Are there in the social sciences instances of paradigmatic upheavals comparable to those created by Copernicus, Newton, Darwin, or Einstein? Can the theories of Keynes, Freud, Chomsky, or Parsons be described as paradigmatic? In the social sciences, does progress occur through paradigmatic revolutions or through cumulative processes?

For there to be a paradigm, one condition must be met: theories must refer to essential aspects of social reality. However, the more ambitious a theory is, the less it can be directly tested by the data available. In the social sciences there are no 'fundamental discoveries,' as there sometimes are in the natural sciences. Instead, unverifiable theories are constructed, partly because social reality itself changes. Kuhn held that a paradigm shift occurs when two 'incommensurable' paradigms are in competition. Then, each school rejects the premise of the others, and contests their work. Communication breakdown is the sign of an incompatibility. In the social sciences such 'incommensurability' takes the pattern of mutual ignorance.

2. Mutual Ignorance

There are two kinds of mutual ignorance: involuntary and deliberate. The formal disagreement may be based on personal rivalries, on contest about priority, on methodological quarrelling or on ideological hostility.

Within a formal discipline, several major theories may cohabit, but there is a paradigm only when one testable theory alone dominates all other theories and is accepted by the entire scientific community. When

Pasteur discovered the microbe, the theory of spontaneous generation collapsed: contagion became the new paradigm. In the social sciences, however, we see at best a confrontation between several nontestable theories. Most of the time there is not even a confrontation but careful mutual avoidance, superb disregard on all sides. This is relatively easy, owing to the size of scientific disciplines, and their division into schools; it is true for all countries, big or small.

This mutual disregard is an old practice in the social sciences. At the turn of the twentieth century, the great scholars did not communicate, or very little. In the writings of Weber there is no reference to his contemporary Durkheim. Yet Weber was acquainted with Durkheim's journal, *l'Année Sociologique*. For his part, Durkheim, who could read German, makes only one, fleeting reference to Weber. Yet they worked on a number of the same subjects, such as religion.

As Giddens puts it:

Weber certainly knew of the work of Durkheim but there can be little doubt that he was barely influenced at all... The same applies in a reciprocal vein; Durkheim knew of Weber's work, and there is a minor reference to aspects of it in one passage in Durkheim's writings, but he claimed no particular kinship with those of Weber's ideas with which he was familiar (Giddens 1987, p.182).

Durkheim does no more than mention in passing Simmel and Tonnies.

Harshly criticized by Pareto, Durkheim never alluded to Pareto's work. Pareto's judgment of Durkheim's book on suicide was unfavorable. 'Unfortunately,' he wrote, 'its arguments lack rigour.' Weber seems to have been unaware of Pareto's theory on the circulation of elites, and Pareto in his turn says nothing about the Weberian theory of political leadership. There was no exchange between Weber and Freud. Ernst Bloch and Georg Lukacs met regularly with Weber in Heidelberg, but their work shows no sign of his influence. The only one of Weber's contemporaries who referred to him was Karl Jaspers, but he was a philosopher (compare Mommsen and Osterhammel 1987).

Weber and Spengler had not exerted the slightest influence on the ideas of the other. Croce said about Weber: 'I had met Weber in 1909. I had no further contact with him, nor did I follow his scholarly work, from which I had only read his early book *Roman Agrarian History*.' As was noted by Raymond Aron, each of the three great founders of sociology followed a 'solitary path.' There is no room for two theorists like Parsons and Sorokin in the same habitat; the clash between them became inevitable. The Parsonian grand theory had a short life. Robert Dahl and Arnold Rose refute the theory of C. Wright Mills; they do not adopt the stratagem of deliberate ignorance—they contest it openly. On the other hand, C. Wright Mills chooses to

ignore the books published by Berle and Means and by James Burnham, in spite of his own theory.

Mosca had accused Pareto of plagiarism. The imprecision of the language of both elitist theorists, who adopted synonyms with confusing meanings, has generated in Italy in enormous literature with the participation of dozens of Italian scholars debating the priority of the authors of the 'political class' and of 'political elites' (Albertoni 1983). Pareto and Mosca are not mentioned by José Ortega Y Gasset (1883–1955). Schumpeter does not refer to Mosca, Pareto, Michels, or Burnham. Angus Campbell and Paul Lazarsfeld have spent a large part of their parallel life in the study of the same political behavior; they never cite each other. Johan Galtung and Stein Rokkan born in 1930 and 1921 respectively, both citizens of the same small country (Norway), have each contributed a theory of 'center versus periphery.' They have never collaborated, avoiding each other carefully; they coexisted by ignoring each other.

Three lists of major contributions to economics were compiled in 1982 at a symposium in Berlin. The first, prepared by W. Krelle, contained 30 names, the second, by J. Tinbergen, 36 names, and the third, by B. Fritsch and G. Kirchgässner, 44 names. In the first two lists, there were only two names that were the same (including Klein, Nobel prize winner, and Krelle himself?); in the first and the third, there were only nine that were the same. The second and third lists did not have a single name in common (Platt 1986, p. 350). Such widely differing views about leading figures do not say much for the coherence of economics. This is also the opinion of the economist Kenneth Boulding, who speaks of economics as being 'disorientated,' comparing it with the story of the blind man and the elephant. The Nobel prize winner Wasily Leontieff was not more indulgent: 'Year after year, economic theorists produce mathematical models without being able to get any further towards understanding the structure and functioning of the real economic system' (quoted in Platt 1986, p. 350). The monetarist George Stigler objected to six econometricians (Tinbergen, Samuelson, Malinvaud, Moore, Frisch, and Fisher) being described as the authors of 'exceptional contributions' because, he wrote, 'econometrics has no unified core or methodology' and 'has not yet had a major impact on economics' (Platt 1986, p. 342). But three of these six economists have since then won the Nobel prize, as has Stigler himself. 'The existence and unity of a discipline called economics reside in the eye and mind of the beholder. Samuelson, Solow, and Tobin and others reserved their harshest words for neoclassical economists like Friedmann and members of the Chicago School, who ridicule Keynes's consumption function' (Amariglio et al. 1993, pp. 150 and 175). The same remarks can be made with reference to other disciplines, except linguistics.

If scholars belonging to the same generation and working on the same subjects ignore each other,

whether involuntarily or deliberately, how could one perceive the existence of a scientific community able to adhere to a common paradigmatic *Weltanschauung*? Paradoxically, the closer the proximity, the more vivid is the rivalry and the more frequent the mutual ignorance. To the isolation of scholars motivated by competition should be added the weak communication between specialties within the same discipline (see *Specialization and Recombination of Specialties in the Social Sciences*).

The absence of consensus among contemporaries is compensated by the transmission of knowledge from one generation to the next, as revealed by citation patterns, particularly in handbooks and compendia. Such a generational transmission testifies that in social sciences scientific advancement occurs mostly by cumulative knowledge.

3. Cumulative Knowledge

Science consists largely in the adding of successive layers of sediments, which form a patrimony for each discipline and field. In all sciences 'the extent of the innovation that any individual can produce is necessarily limited, for each individual must employ in his research the tools that he acquires from a traditional education, and he cannot in his own lifetime replace them all' (Kuhn 1970, p. 183). Progress does not arise in a vacuum, but develops out of the scientific patrimony. It is difficult to find in the social sciences a virgin domain. Every decade that passes adds layer upon layer to the patrimony, the only recent exception being the 1930s in Europe. New explanations supersede older interpretations. Many examples of cumulative progress can be given. Even giants rely on the patrimony. Karl Marx refers to Adam Smith on 296 of the 1,721 pages of his *Theory of Surplus Value*. In this book he draws on the work of his predecessor in more than one page out of every six. Ralf Dahrendorf cites Marx 160 times (Dahrendorf 1957). Max Weber does not cite Karl Marx, but many of his writings were a reply to the thesis of his predecessor. He once noted that he could not have accomplished crucial parts of his work without the contributions by Marx and Nietzsche.

Darwin had recognized his debt to Malthus; Keynes would not have been able to write one of the most famous books of the twentieth century without the incremental advance achieved by several generations of economists. The 'theory of development' consists of a long chain of accumulated contributions in several disciplines.

The literature on elites is a good example, among others, of cumulative knowledge even in the case of mutual ignorance. Many contributions emphasize the sedimentation of layers of knowledge. The old Mosca–Pareto layer, impregnated with plagiarism, has become consolidated groundwork. Two dozen

important books published since 1950 have built an impressive patrimony. Obsolete theories have served as fertilizers for new complementary theories. One example of cumulative knowledge is the new influence of electoral techniques on party systems. A bibliography, even a very selective one, on this theme could easily list 200 or 300 titles in English, not to mention the many varied observations derived from the direct experience of politicians in numerous countries. From Condorcet, Bachofen, John Stuart Mill, Hare, and Hondt to Hermens, Downs, Duverger, Sartori, Lijphart, the theory is based on the contributions and successive improvements made by a very large number of scholars. (For example, the consequences of proportional representation were described by Bachofen as long ago as 1850).

For each of the dozens of important domains in the social sciences there is a substantial patrimony, the accumulated knowledge of a long chain of scholars. Imagine the following imposture-exercise. Take from the literature a classic article or chapter, for instance Max Weber's seminal chapter on 'Domination and Legitimacy,' falsify the name of the author, make a few cosmetic changes, and offer it to a major journal. Would such a manuscript be accepted today? Would not a paper that ignores the literature of the last decades preclude publication? The patrimony is common property. Although every concept or theory or method has its creators and developers, they do not need to be cited every time the term is used. Even the identity of the originator may disappear into anonymity. We do not, and cannot, remember who used for the first time terms such as 'role,' 'revolution' or 'social mobility.' Given such a patrimony, scholars today can start their research at a much higher level than did their predecessors (Dogan and Pahre 1990, p. 21). A graduate student today knows more than the founders of his or her field—even if they do not have the reasoning capacity of their forebears. That knowledge is largely acquired by cumulation is an obvious fact for all sciences; if it were otherwise, simultaneous discoveries in the natural sciences would not occur, theoretical debates in the social sciences would not be engaged. They are generated when the issue is 'in the air,' when 'time is ripe.' The dispute between Mosca and Pareto about the paternity of ideas in elite studies is similar to the dispute between Newton and Leibnitz about priorities on calculus. In elite studies, for variety of reasons 'the time was ripe' at the end of the nineteenth century. 'Discoveries are like apples on a tree,' wrote Price (Kuhn 1986, p. 60). In the history of social sciences some books have played a crucial role but they are only summits in a chain of mountains, not paradigmatic contributions in the sense given to this word by Thomas Kuhn.

Overarching theories, that is, paradigmatic frameworks, can be built on more solid ground in the natural sciences than in the social sciences, because in the former truth is universal, in the later, contextual.

4. Contextual Diversity vs. Universal Truth

Chemical substances keep indefinitely the same composition and are identical in all latitudes. Not so social phenomena! In contrast with the natural sciences, contextual diversity and social change are two important parameters in all social sciences. Both parameters resist ambitious paradigmatic generalizations. Extrapolating Kuhn's perception of the history of astronomy, physics, or chemistry to social sciences is like looking into a distorting mirror. Many concepts and theories do not have equal pertinence when applied to Western Europe and to tropical Africa. Dependency theory may be a pertinent theory for yesterday's Latin America and for Eastern Europe today, but not for other areas in the world. The comparative method reduces the significance of paradigmatic frameworks. Dozens of theories with universal pretensions neglecting national configurations have been invalidated.

In the natural sciences an experience can be repeated many times in identical conditions anywhere in the world (except when magnetism has an impact). On the contrary, social realities change. For instance, at the time of Malthus, overpopulation in Europe was a realistic hypothesis. Today, birth rates in this continent are not sufficient to replace the outgoing generation. Traditional values concerning religion, nation, family, erotism, or authority have changed at an accelerated rhythm in the last decades of the twentieth century. Theories reflecting the social reality one generation ago have to be replaced in order to explain contemporary trends. History never repeats itself because factors do not recombine in identical ways at all epochs. The scope of social sciences is rarely the discovery of laws with universal validity, but rather the explanation of social diversity. 'What is true in one side of the Pyrénées is not in the other side,' wrote Montaigne four centuries ago. In the social sciences truth is not universal, it is contextual. Social scientists do not make inventions, and rarely make discoveries; what they do best is to observe regularities and exceptions (anomalies). It is for this reason, that the most imaginative strategy in the social sciences is the comparative method, the best surrogate for the experimental method. Social phenomena being contextual, paradigmatic statements in political science, sociology, anthropology, social psychology or social history often appear as ethnocentric and misleading.

Most social scientists who adopt the concept of paradigm apply it to particular domains, not to their entire discipline. For some scholars, elitism is the most powerful paradigm against the Marxist paradigm. In the domain of political economy, rational choice is elevated to the rank of paradigm. Many psychiatrists are mobilized around the Freudian paradigm.

Competing theories contribute to the advancement of knowledge. To explain the fall of the Roman empire, 14 competing theories have been formulated

by great scholars, from Montesquieu to Max Weber, to which can be added a theory proposed by chemistry (saturnism). None is fully comprehensive, but each one enlightens part of the phenomenon. The history of social sciences is not a history of paradigmatic upheavals, but of competing theories, with many being invalidated, but many others constituting the foundations of the contemporary social sciences. Without competing theories, social sciences would not advance. The clash of theories leaves no room for paradigms.

A symptomatic analogy can be drawn between what Kuhn calls in the revised version of his theory, 'scientific community' (adepts of a paradigm) and what some social scientists (Almond, Merton, Smelser, Zuckerman) call 'school.' In the recent history of social sciences there are dozens of schools: monetarist, rational-choice, bio-social, individualist, postmodernist, and so on, and that means that attempts to formulate overarching disciplinary paradigms may appear as 'imperialist views.'

As Merton put it:

Since all virtues can readily become vices merely by being carried to excess, the sociological paradigm can be abused almost as easily as it can be used. It is a temptation to mental indolence. Equipped with his paradigm, the sociologist may shut his eyes to strategic data not expressly called for in the paradigm. He may turn the paradigm from a sociological field-glass into a sociological blinker. (Merton 1957, p. 16).

In some cases a paradigm may assume the features of a dogmatic orientation. No wonder if not so many scholars adopt it: 'The notion of paradigms and paradigmatic revolutions often seem to be taken up only in order to be rejected. The beneficiary of this exercise in several cases is Lakatos, mostly because he appears as a type of moderate Kuhn' (Weingart 1986, p. 267). In the social sciences, theoretical disagreements are beneficial to the advance of knowledge. Nevertheless, the word paradigm has taken root, particularly in sociology, political science, psychology, and normative philosophy. Yet most philosophers of science reject it; most historians are reluctant to make such generalizations; most economists continue to think in terms of assumptions. It may be too late now to try to exclude this word from the lexicon, in spite of the fact that many other expressions are available (conceptual framework, assumption, dominant theory, theoretical breakthrough, grand theory, general model, axiom, and so on). It has become necessary to specify it, or to limit its use to particular domains, such as cognitive science, international relations, or hybrid demography.

Para-lawyers: Other Legal Occupations

1. Definition

Para-lawyers are persons performing 'law work' who themselves are not lawyers. Law work in turn refers to those activities requiring at least some of the specialized legal knowledge and skill of the type associated with the work of lawyers. Thus, para-lawyers are 'law workers' who lack the full credentials and/or status associated with the legal profession but who provide services that draw on expertise in law and/or legal processes. This negative definition reflects the complexity of defining the practice of law and what constitutes membership in a legal profession.

Drawing the line between lawyers and para-lawyers varies from country to country because of variations in the nature of legal tasks within different legal

systems, and how those tasks are assigned to particular occupations. In many countries, the exact line is not clear. In some countries, the term most equivalent to 'lawyer' is customarily applied to an occupation engaged in a very narrow range of activities, while there are other occupations requiring substantial formal legal training that perform work which elsewhere would be the exclusive domain of the legal profession. Deciding whether to include such occupations under the label lawyers or para-lawyers requires drawing an arbitrary line. One example is the legal occupation of 'notary' as it exists in many civil law countries (Malavet 1996). Historically, the occupation of notary arose to provide a neutral person who could be trusted to draw up fair contracts to be executed by one or more persons unable to read or write; today, notaries continue to play a role in the drawing up of and execution of contracts, and apply specialized legal knowledge related to those activities. If the notary's tasks involve anything more than ministerial functions such as witnessing the execution of contracts, it is arbitrary whether or not the notary is part of the legal profession or should be categorized as a para-lawyer.

In addition to problems of drawing a line between lawyers and para-lawyers, it is difficult to draw a line between para-lawyers and 'nonlaw' occupations. For example, many nonlaw occupations require the use of some very specific legal knowledge, typically applied in a very routine way. Examples include drawing up contracts for routine property transactions (in the United States typically done by real estate sales agents), drawing up routine loan contracts (done by bank officials), settling tort-based injury claims (done by nonlawyer representatives of insurance companies), or advising on estate or tax issues (done by financial advisors and accountants). In one sense, all of these occupations could be labeled para-lawyers; for some of the occupations the para-lawyer work is only a part of their activities (e.g., real estate sales agents) while for others (e.g., insurance claims representatives) it is the vast bulk of their work.

Finally, there is no recognized standard of education or specialized training to become a para-lawyer. While there are training courses for occupations variously labeled 'paralegal,' 'legal assistant,' or 'legal executive,' these courses do not provide formal qualifications, and most people enter such occupations without any formalized training (Johnstone and Wenglinisky 1985, pp. 121–3). Other kinds of para-lawyer occupations involve the application of knowledge learned in some other role; examples include former police officers representing persons charged with driving while intoxicated in Ontario, former Internal Revenue Service (IRS) auditors representing or assisting taxpayers in disputes with the IRS in the United States, former insurance company claims inspectors or adjusters representing injury claimants in England, and legal secretaries who take on in-

creasing responsibilities to the point where they are engaged more in law-work than in secretarial work. Thus, there is no clear way to decide whether a person offering a particular set of services, or engaged in a particular set of tasks, should be classified as a para-lawyer; nor is the term para-lawyer in common use in a way that would allow for self-identification.

2. Empirical and Theoretical Issues

Even with these definitional and boundary problems, the concept of para-lawyers, and para-professionals more generally, is useful theoretically and important for practical purposes. It raises the issues of how law-work is and should be structured, and what qualifications are needed to be effective in law work. In addition, there are two other lines of theoretical inquiry that are important vis-a-vis para-lawyers: 'deprofessionalization' and the gendering of occupations.

2.1 Structure of Law Work

Law work readily divides along at least three dimensions: institutional setting, legal advice vs. legal assistance, and routine vs. nonroutine tasks. The degree to which para-lawyers have in the past, and are today, providing legal services varies along these dimensions. As one moves among institutional settings—from office, through tribunal, to lower courts, and finally to the higher courts—the role of para-lawyers tends to decrease. Para-lawyers are most often excluded from law work in upper level trial and appeal courts, and least often from tasks that can be completed in the privacy of an office. For example, in England, lawyers enjoy a monopoly on representation in the higher courts; in contrast, office-based work generally is not limited to lawyers, nor is representation before administrative tribunals. Recent developments are bringing nonlawyers into some courts in England, particularly to handle preliminary matters in criminal cases.

Continuing with the example of England, para-lawyers direct a larger proportion of their effort toward providing advice on legal matters, broadly defined, while lawyers are more likely to engage in active assistance. In part this is because accounting firms and advice bureaus staffed by nonlawyers are major providers of legal advice in England. In other countries, it is likely to be the case that para-lawyers are more involved in advice-giving simply because it is less visible, and hence difficult for regulators to limit or otherwise control.

The more that routines can be established to handle a legal task, the more possible it is for someone with very specific training and/or expertise to handle the task, even if it is highly technical. For example, in the

US, appeals of certain types of government benefit claims involve highly technical issues of both regulations and medical assessment. Such cases tend to be handled by specialists, some of whom are lawyers and some of whom are para-lawyers. On the less technical side, there are many legal processes that are routine but require the completion of various kinds of forms; para-lawyers can both identify the forms needed for various processes and assist consumers in the completion of those forms.

One final issue concerning the structure of legal work and para-lawyers is whether they work as independent service providers or under the supervision of lawyers. Many lawyers employ para-lawyers to complete routine and/or specialized tasks within the lawyers' practices (Johnstone and Wenglinisky 1985); many legal departments inside organizations employ a mix of lawyers and para-lawyers all under the supervision of senior lawyers. Typically, para-lawyers working under the supervision of lawyers is an accepted delegation of responsibility, although there is substantial variation in drawing the line between what a para-lawyer may do and what requires a lawyer. One frequent boundary is the courtroom door: representation in court tends to be limited to lawyers, although that may be less so in the lower courts (the example of drunk driving cases in Ontario noted previously), and is changing under both political and economic pressures (the example of para-lawyers handling certain criminal matters in England, and the role of specialized advocates in certain types of cases such as domestic violence).

2.2 Effectiveness in Delivery of Legal Services

A key question with regard to the work of para-lawyers is how it compares in quality to the same activities carried out by lawyers. While lawyers claim that use of para-lawyers raises threats of poor quality work, efforts to compare systematically the work of lawyers and para-lawyers fail to support this contention (Kritzer 1998). The extant research demonstrates that para-lawyers can be as effective as lawyers in providing specific legal services. Achieving effectiveness involves a combination of specific knowledge or expertise vis-a-vis substantive law, institutional process, and other actors in the system. Para-lawyers who obtain this combination can achieve levels of effectiveness comparable to that of lawyers, and specialized para-lawyers will tend to be more effective than lawyers lacking one or more of the three core elements of knowledge.

The relationship between the service provider and the client can also influence the relative effectiveness of the provider. Specialist para-lawyers who have ongoing relationships with clients may be more effective than even specialist lawyers brought in on an *ad hoc* basis to handle a specific matter; this reflects the

knowledge base created by the ongoing relationship. The payment arrangement between service provider and client may also make a difference. One study that found specialist lawyers to be more effective than specialist para-lawyers in a particular area attributed the difference in significant part to the lawyers being paid on a no-win, no-fee basis while the para-lawyers' compensation was unaffected by the outcome of specific cases.

2.3 Deprofessionalization and Postprofessionalism

'Deprofessionalization' refers to the shift from professional to nonprofessional status. Professional status is conferred on those occupations which maintain a monopoly over a theoretical base of knowledge, have expectation of autonomy in regulation and day to day work, and have among their clientele a belief in the professional having a service ethos. Deprofessionalization refers to the loss of these supposedly unique occupational qualities (Haug 1973, Rothman 1984). Nonprofessionals such as para-lawyers increasingly do work once the province of professionals.

Deprofessionalization reflects several specific developments. First is the combination of the rationalization of knowledge, the rationalization of tasks employing knowledge, and the growth of tools to assist in applying knowledge. The more that tasks can be compartmentalized and the more that knowledge-based tools can be applied, the easier it is to assign the task to a person with limited, specific expertise. The result is the deskilling of knowledge-based occupations. A second development is the loss of governmental support for restrictions limiting the role of para-lawyers. In England solicitors held a monopoly on handling land transfers for many years, but these tasks are now open to licensed non-lawyer specialists; in the US, limitations have been under attack politically at both the national and state level (Commission on Nonlawyer Practice 1995). The third development is the increasing bureaucratization of legal service delivery; once organizational structures become established, there is a drive to rationalize, compartmentalize, and reduce costs. Bureaucratic structures also provide means for supervision and control, which both creates tensions for professionals expecting autonomy and provides a setting to monitor the work of para-lawyers.

A traditional claim by lawyers seeking to secure and maintain restriction on the delivery of legal services is that opening such work to para-lawyers and other nonlawyers jeopardizes the interest of clients both because of lack of competence and the absence of the stringent ethical norms of the professional. As noted in the previous section, systematic research in the United States and elsewhere increasingly challenges this claim. The loss of this argument combined with drives to contain costs through broadening options in

service-oriented markets pushes toward less and less control of 'professional' services.

The concept of deprofessionalization suggests the loss of something. An alternative concept, 'postprofessionalism' (Kritzer 1999) reflects most of the same elements but sees the opening of legal and other professional services to para-professionals such as para-lawyers as part of a natural development. Postprofessionalism builds on the growth of technological tools to access knowledge previously the exclusive realm of persons with professional-level training (Susskind 1996). These developments parallel the industrial revolution when the rationalization of tasks and the development of machines led to the shift from crafts-based production to factory-based production. Postprofessionalism captures the image of a similar shift for people who work with their heads rather than their hands: rationalization of knowledge combined with information technology tools make it possible to produce services using workers with lower levels of training and knowledge.

2.4 Gendering of Occupations

A final issue in the analysis of para-lawyers relates to the gendered nature of occupations. Historically, professions have been male-dominated while many para-professions have been female dominated. Within law-work, women were largely excluded from the professional ranks until about 1970. In the early twentieth century some of the American states formally excluded women from the bar; even where they were not excluded, women were often confined to roles such as legal secretary even if they had the formal credentials of a law degree. Since 1970, most countries have witnessed the opening of the legal profession to women, and the number of women who practice as lawyers has increased sharply.

Nonetheless, para-lawyer roles tend to be dominated by women; this is particularly true of para-lawyer positions that are specifically subordinate to lawyers (Johnstone and Wenglinisky 1985, p. 69). Even for those para-lawyer positions that function independently of lawyers, the gender composition may limit the likelihood of achieving some sort of full professional status as long as they are seen as in competition with the existing legal profession (Hearn 1982). At the same time, efforts to increase occupational status may lead to certain kinds of 'closure' strategies which bear a resemblance to those employed by lawyers: formal licensing, testing requirements, educational qualifications, etc. (Witz 1992, Johnstone and Wenglinisky 1985, pp. 165–6). Whether such efforts ultimately improve status or lock in gendered distinctions is an important theoretical and empirical issue.

A final gender-related issue concerns the professional roles assumed by many of the increasing number of women in the legal profession. A common

observation in the literature on the struggles of women to achieve status and economic parity with men in the legal profession is that women lawyers are disproportionately to be found in law-work positions that are themselves in some sense gendered (e.g., family law practice, as employees rather than as principals, etc.). In some ways, the professional roles occupied by many women lawyers are closer to those of para-lawyers than to the traditional image of the work of male lawyers (Sommerlad and Sanderson 1998). This development may lead to a blurring of lines between lawyers and para-lawyers while preserving patriarchal status structures in the workplace.

3. Future Research and Theory

As theoretical and empirical concepts para-lawyers and para-professionals more generally, are underdeveloped. Current dynamics in the changing occupational structures, such as postprofessionalism, suggest that the para-lawyers should become increasingly important in the study of law work and in the delivery of legal services. The relationship of para-lawyers to the increasing role of information technology is one avenue of potential theory and research; a second is the economics of service delivery; and a third potential area is in the relationship of para-lawyer occupations to broader patterns of changing social structures, particularly the changing impact of gender on social structure.

H. M. Kritzer

Parapsychology

According to *The Journal of Parapsychology* the term 'parapsychology' designates 'The branch of science that deals with *psi* communication, i.e., behaviorial or personal exchanges with the environment which are extrasensorimotor—not dependent on the senses and muscles.' The same source defines 'psi' as 'A general term to identify a person's extrasensorimotor communication with the environment.' Psi includes ESP and PK, 'ESP' (extrasensory perception) is defined as 'Experience of, or response to, a target object, state, event, or influence without sensory contact.' ESP includes telepathy (mind to mind communication without normal channels of communication), clairvoyance (extrasensory contact with the material world), and precognition (the knowledge of future events that cannot be inferred with present knowledge). The other component of psi, PK (psychokinesis) is defined as 'The extramotor aspect of psi: a direct (i.e., mental but nonmuscular) influence exerted by the subject on an external physical process, condition, or object.'

J. B. Rhine adapted the term parapsychology from the German word *Parapsychologie* in the 1930s to replace the earlier term *psychical research*. More than a change in terminology was involved. Psychical research covered a broad range of systematic investigations into spiritualistic phenomena, haunted houses, premonitory dreams, visions, and the like. Rhine's program avoided much of this material, especially that which dealt with questions of survival after death. Instead, he emphasized controlled laboratory experiments using normal individuals as subjects. Thus, the change in terminology signaled that parapsychology aspired to become an accepted scientific discipline.

1. Historical Background

1.1 Scientists and Psychic Phenomena

In 1848, the two young sisters Margaret and Katherine Fox initiated modern spiritualism with their demonstrations of rappings and other material phenomena which they claimed were caused by the spirits of dead people. Soon many other individuals, calling themselves mediums, were regularly producing phenomena which they attributed to spirits of the dead. Because science deals with material phenomena, and because

material phenomena were what the spiritualists were offering as support for their paranormal claims, some major scientists became interested in investigating these claims. In 1853, Robert Hare, an important chemist from the University of Pennsylvania, began an investigation of table-tilting. He attended seances where he became convinced that the spirits of the dead were moving the tables.

In 1865, Alfred Russel Wallace, the cofounder with Darwin of the theory of evolution through natural selection, began his investigations of spiritualistic phenomena. He quickly became convinced of the reality of the paranormal and for the remaining 48 years of his life he continued his investigations and outspokenly defended the reality of spiritualistic phenomena. Sir William Crookes, the discoverer of thallium and the inventor of the cathode ray tube, began his investigations of the paranormal in 1869. He concluded, to the dismay of his scientific colleagues, that a psychic force was operating in these seances.

1.2 The Society for Psychical Research

Inspired by the investigations of such eminent scientists as Hare, Wallace, and Crookes, a group of scholars and spiritualists formed The Society for Psychical Research in London in 1882. The philosopher Henry Sidgwick, its first president, stated that the goal was to collect more evidence of the kind that had been reported by those scientists who had investigated mediums. Although Sidgwick believed that the previous investigations of mediums had already provided evidence sufficient to prove the existence of the paranormal, he was aware that the majority of the scientific community were not convinced. Therefore, the aim of the Society was to accumulate enough additional evidence of the same sort so as to force the scientific community to admit that the case for the paranormal had been proved or to accuse the proponents of insanity or gross incompetence.

In his inaugural presidential address, Sidgwick claimed that, in fact, some members of the new society had already collected just the sort of evidence that proved beyond a doubt the existence of telepathy. Sidgwick was referring to the investigations involving the Creery sisters. Unfortunately, the Creery sisters were later discovered to be signaling to each other using a code. Although an attempt was made to claim that such a code could not have accounted for some of the results of their investigations, this body of evidence was subsequently removed from the republished proceedings of the Society for Psychical Research. A similar fate befell the very next set of investigations which the Society originally offered as solid proof for the existence of telepathy. These investigations involved two young men, Smith and Blackburn, who apparently could communicate with each other tele-

pathically. Many years later, Blackburn published a confession of how he and Smith had tricked the investigators. This case was also deleted from later printings of the Society's proceedings (Hyman 1985a).

2. From *Psychical Research* to *Parapsychology*

2.1 J. B. Rhine

Joseph Banks Rhine and his wife Louisa came to Duke University in 1927 and developed a program of research based on card guessing experiments. They termed their program 'parapsychology' and focused their efforts on making this discipline into an experimental science. They replaced the regular deck of playing cards with a deck consisting of five distinct symbols—a circle, a square, three wavy lines, a cross, and a star. Each symbol occurred five times, making a deck consisting of 25 cards. The same set of cards could be used as targets for experiments in telepathy, clairvoyance, and precognition. In addition, the symbols could be presented in a variety of ways.

In a typical clairvoyance condition, for example, the deck would be shuffled and the subject would be asked to guess the symbol of each card at each location in the deck. Since there were five different symbols, the subject had one chance in five of being correct on each guess just by chance. In other words, the subject would be expected to average five correct hits on each run through a deck of 25 cards. In a precognition test, the subject would make his or her guesses before the deck was shuffled. In a telepathy test, a sender would look at the symbol on each card at the time the subject was making his or her guess.

When Rhine published his first monograph, *Extra-Sensory Perception*, in 1934 he had collected data on a total of 91,174 guesses in three years. The average number of hits per run of 25 guesses was 7.1 as compared with the chance expectation of 5. Although the results were barely 2 hits per deck higher than the expected 5, the probability of such a departure from chance, given the huge number of trials, is very low.

The scientific community, at first, took great interest in this outcome. Never before had so much scientific data been amassed in favor of a paranormal claim. After some years, however, skepticism and criticism from the scientific community prevailed. In part, this was because several attempts by independent investigators to replicate these findings failed. In addition, criticisms were aimed at both the statistical procedures as well as the experimental controls. For the most part, the statistical criticisms turned out to be unfounded or insufficient to explain away the results. The methodological critiques were more serious, and gradually parapsychologists improved their procedures for preventing sensory leakage, randomizing the targets, specifying the criteria in advance, and the like.

The paradigm that Rhine initiated under the rubric of parapsychology transformed psychical research into a serious contender for a place among the accepted sciences. It also established the basic procedures for parapsychology for a period covering the years from 1930 to around 1970. During this time the ESP cards were the predominant stimulus for experiments in telepathy, clairvoyance, and precognition. Rhine also initiated the study of psychokinesis (PK) by having subjects attempt to influence the outcomes of dice tosses. The full story of the first couple of decades of this formative period is recounted in Mauskopf and McVaugh (1980).

2.2 S. G. Soal

As already indicated, the problem of replicability haunted the early results of Rhine's card-guessing experiments. Rhine and other US parapsychologists claimed that their results, when they were successful, were equally good for telepathy and clairvoyance trials. The British parapsychologists, however, claimed that their successful experiments only involved telepathy and never clairvoyance. Perhaps the strongest critic of Rhine's early work was the British mathematician, S. G. Soal. During the years 1934–9, Soal managed to amass 128,350 guesses from 160 percipients. He reported that the number of hits was just what would be expected by chance.

A fellow parapsychologist, Whately Carington, eventually convinced Soal to review his data to see if some of his percipients might reveal a 'displacement effect.' Perhaps, he suggested, some of the subjects' guesses were systematically off by one or two targets. Soal, indeed, discovered that two of his 160 subjects showed significant hitting above chance when their guesses were matched not against the intended target but, instead, against the target for the next trial.

Soal realized that finding such displacement patterns in two out of 160 subjects after the fact could be a statistical quirk. He was able to find and persuade one of these subjects, Basil Shackleton, to participate in 11,378 more guesses during the years 1941–3. As was the case in the original experiment, Shackleton's guesses, when matched against the actual target, were consistent with chance. However, when compared with the symbol that came after the target (precognitive hitting), his guesses were well above chance. Soal reported the odds against chance for such a pattern as 10^{35} to 1. Beginning in 1945, Soal was able to gather 37,100 guess from the second subject, Gloria Stewart. Unlike her previous results or those of Shackleton, Mrs. Stewart showed no displacement effect. Instead, her guesses of the intended target were significantly above chance. Soal calculated the odds against chance of this outcome as 10^{79} to 1.

Such strikingly successful results over a period of years, especially from a strong critic of Rhine, caught

the attention of both parapsychologists and skeptics. Parapsychologists hailed the experiments as definitive proof of psi. Critics looked for possible flaws or weaknesses. The early critics managed to find some suspicious patterns, but nothing conclusive. Some proposed fanciful scenarios, involving the collusion among several investigators, to account for the results.

It wasn't until 1978 that Betty Markwick published her findings which convinced most parapsychologists and all the skeptics that Soal had indeed cheated (Hyman 1985a). Ironically, Markwick made her discovery while she was carrying out an elaborate investigation to vindicate Soal's reputation. As part of her plan, she searched tables of logarithms for matches to sequences of targets in Soal's experiments. Because Soal had claimed that he had used Chambers' tables for his random sequences, Markwick reasoned that if she could find matches between Soal's target sequences and sequences in Chambers' tables, this would show that, at least, Soal had not tampered with the target sequences. What she found were partial matches. Many of Soal's sequences had extra insertions within the sequence and these extra insertions usually corresponded with hits. The strong implication was that Soal had deliberately constructed his target sequences with blank spaces inserted systematically. In recording the percipient's guesses, he could surreptitiously insert target numbers in the blank spaces that would match the guess for that trial. Such insertions would suffice to bias the results towards a highly significant, but spurious, outcome.

2.3 *The Post-Rhine Era*

Around 1970, Rhine's specific targets and procedures began to be discarded in favor of new targets and procedures. The striking successes of the early 1930s were no longer in evidence. Results were inconsistent, replicability was still elusive, and the hit rate—even in the few successful outcomes—had become very small. Cynics attributed the declining hit rate to better controls and other methodological and statistical improvements.

Most parapsychologists, however, blamed the weak or nonexistent effects to the austerity of Rhine's procedures. The targets on the ESP cards were meaningless and abstract. The constraint on the subjects' responses to just one of a few choices and the rigidity of the experimental plans all conspired, in the view of many parapsychologists, to dampen the delicate ESP ability.

So parapsychologists began using targets that were emotionally and otherwise meaningful—actual photographs, motion picture clips, actual physical sites, etc. They also eschewed the forced-choice methods of Rhine in favor of free-responding, i.e., the percipients were encouraged to say whatever came to mind and to describe their 'mentation' in whatever words they

chose. In addition, they began to take advantage of new technological breakthroughs, especially video and computer developments. These more natural targets and fewer constraints upon the subjects' responding made problems of control and scoring more complicated, but parapsychologists felt that this was a small price to pay in order to achieve what they call psi-conducive conditions.

3. *The Contemporary Scene*

Contemporary parapsychology has generated a variety of novel approaches. Computers are central to much of the research. A line of research that goes back to the late 1960s involves having subjects attempt to influence psychically the output of random number generators (RNG). Computers are also used to control many of the aspects of conducting experiments such as selecting targets, recording the guesses, reporting the outcomes, etc. Advances in neuroscience are also exploited and many experiments use physiological indices instead of, or in addition to, verbal responses. Among these new approaches, three lines of research predominate. The research on remote viewing began in 1972 at the Stanford Research Institute. Until 1995, much of that research, conducted under the auspices at first of the CIA and later the Defense Intelligence Agency was classified. The work was declassified in 1995 and evaluated by a panel consisting of the statistician, Jessica Utts, and the psychologist, Ray Hyman. Hyman and Utts disagreed about the scientific status of remote viewing. Utts concluded that the evidence clearly supported the existence of psi and Hyman that the scientific claim had not been proven. Both agreed, however, that the results of remote viewing were too unreliable to justify using them for information gathering.

The second line of research, initiated by Helmut Schmidt in 1969, involves having subjects attempt to influence or bias the outputs of random number generators (RNGs). Although many different investigators and laboratories have published research on apparent psychokinesis or PK effects on RNGs, the overwhelming number of trials in this line of research has come from the Princeton Engineering Anomalies Research (PEAR) program at Princeton University under Robert Jahn and his associates. In 1987, Radin and Nelson (Radin 1997) conducted a meta-analysis of the RNG experiments conducted from 1959 through 1987. A meta-analysis is a method for combining or pooling the results from several previously published reports involving similar procedures. They reported that the combined outcome produced an effect with odds against chance of more than a trillion to one. Radin claims that the results of such studies completed since 1987 are still consistent with that meta-analysis.

Despite these claims for the RNG research, the studies have been criticized on a number of grounds. Although the meta-analysis pools the data from all the laboratories, the pooling does not deal with the various and different patterns of outcomes from separate laboratories. For example, the PEAR researchers claim to have found a distinct pattern: The RNG outputs slightly more positive units when the subject is trying to influence it in that direction and slightly more negative units when the subject is trying to bias the output in the negative addition. In the neutral condition, the output is evenly divided but the variability is less than would be expected by a truly normal distribution. When the results from these three conditions are pooled the distribution becomes perfectly normal with a mean of zero. No other laboratory has replicated this interesting pattern. The replicability that Radin and Nelson claim is a rather weak one. In effect, any departure from the chance baseline, no matter the specific pattern, is considered equal to any other departure. The one physicist who has deliberately tried to replicate Jahn's RNG findings, Stanley Jeffers, has failed to do so.

3.1 The Ganzfeld-psi Experiments

The line of research that has had the most influence since the early 1970s and is at the center of parapsychology's claim of a demonstrable psychic anomaly is the ganzfeld-psi program. The March 1985 issue of *The Journal of Parapsychology* was devoted to 'The Ganzfeld Debate.' This debate consisted of a 47-page critique by Ray Hyman of the 42 ganzfeld-psi experiments known to exist at that time. This was followed by a 47-page response by Charles Honorton, one of the pioneers of this type of experiment.

Hyman (1985b) agreed that, taken as group, the overall hit rate in the ganzfeld experiments exceeded what would be expected by chance. However, he identified a number of statistical and methodological flaws characterizing the experiments. These were flaws which parapsychologists recognize as ones that should be avoided. Yet, not one of the experiments in this data base was free of all the flaws. Hyman concluded that, given the various flaws, the alleged significant levels had been vastly overinflated and the set of experiments could not be used to draw any conclusions about the existence of psi.

In his response, Honorton (1985) devised a different method for assigning flaws and concluded, contrary to Hyman, that the flaws, while there, had no impact on the outcome of the experiments. The controversy continued with parapsychologists supporting Honorton's analysis and the skeptics supporting Hyman's. Rather than continue with further responses and rebuttals, Hyman and Honorton collaborated on a joint paper to focus on areas of agreement and to suggest guidelines for future ganzfeld-psi research (Hyman and Honorton 1986).

In 1990 Honorton and his colleagues published an article in the *Journal of Parapsychology* (Honorton et al. 1990) which summarized six years of new ganzfeld-psi experiments supposedly meeting the guidelines devised by Hyman and Honorton. The new set of experiments, mainly controlled by computers, became known as the autoganzfeld experiments. The hit rate was consistent with the previous set of ganzfeld experiments and was highly significant. In 1994, a major psychological periodical, the *Psychological Bulletin*, published the article 'Does psi exist? Replicable evidence for an anomalous process of information transfer' jointly authored by the psychologist Daryl Bem and Charles Honorton (Bem and Honorton 1994) (unfortunately, Honorton died before the article was published). The same issue contained a commentary by Hyman (Hyman 1994) as well as a 'Response to Hyman' by Daryl Bem (Bem 1994).

Hyman questioned the claim by Bem and Honorton that the autoganzfeld findings were consistent with the original ganzfeld data base. He discovered two peculiar and striking patterns in the autoganzfeld data. While Hyman found these two patterns suggestive of an artifact, Bem responded that if it turned out to be a property of psi, parapsychologists should call it the Hyman Effect.

The ganzfeld-psi research continues in many laboratories around the world. Radin (1997) describes a meta-analysis of all the ganzfeld-psi studies through early 1997. He concludes that 'The overall hit rate of 33.2 percent is unlikely with odds against chance beyond a million billion to one' (p. 88). This contrasts sharply with the conclusions from a meta-analysis of 30 ganzfeld experiments by Milton and Wiseman (1999). These experiments were conducted after the autoganzfeld experiments and yielded an effect size consistent with zero. Milton and Wiseman 'conclude that the ganzfeld technique does not at present offer a replicable method for producing ESP in the laboratory.'

4. The Case for Psi

The strongest arguments for the reality of psi have been presented by Jessica Utts (1991) and Dean Radin (1997). Both base their case upon meta-analyses of previously published articles. Utts relies upon meta-analyses of the ganzfeld-psi experiments, early precognition card-guess experiments, RNG studies, early dice-throwing experiments, and studies relating extroversion to ESP performance. Radin includes these as well as several other meta-analyses.

The meta-analyses are used to draw two conclusions. The first is that the pooled effect size emerging from each meta-analysis, although small, is sufficiently large to reject the possibility of being due to chance. The second is that no difference in effect size can be traced to differences attributed to flaws in the ex-

perimental procedures because the effect size is essentially the same for methodologically strong and weak experiments.

It is on this basis that parapsychologists such as Utts and Radin conclude that the evidence for psi is conclusive. Radin argues that the case for psi has been made conclusive several times in the past and that the only mystery is why this is not better known. He implies that the public is unaware of the scientific case for psi because of the attempts by skeptical 'gatekeepers' to prevent the public from knowing about it.

5. Grounds for Caution

Despite such strong claims by Utts and Radin, the skeptics insist that there are good reasons for doubting that the evidence for psi is adequate. The meta-analysis of the most recent ganzfeld studies by Milton and Wiseman (1999) strongly suggested that the previous ganzfeld successes cannot be replicated. Worse, Milton and Wiseman found that most of the claims for correlates of psi performance also did not replicate. Although their meta-analysis is controversial, the controversy itself points to major problems with trying to base the proof of psi on meta-analysis of previously published studies. Critics have pointed out many problems with meta-analyses.

When used properly, meta-analysis can be a useful tool to help generate patterns and hypotheses about a body of data. Such a usage is consistent with what statisticians call exploratory analysis. The mistake the parapsychologists seem to make is to use the same meta-analysis both to find possible patterns and then prove the existence of such patterns. This is like having your cake and eating it too. A meta-analysis is inherently retrospective. The results are best used prospectively to make predictions about specific patterns to be found in new sets of data. So far, parapsychologists have not succeeded in doing this.

6. Prognosis

Although some key parapsychologists argue that their evidence strongly supports the reality of psychic phenomena, the main body of the scientific community remains unconvinced. At best the parapsychologists have demonstrated, by pooling results from previously published studies, that significant departures from the chance baseline occur more often than expected. They have yet to demonstrate, however, that these departures—if real—originate from a common cause. Nor have they demonstrated any lawfulness in these deviations. Worse, they have yet to come close to specifying a set of conditions and procedures that would enable believers and skeptics to reliably observe these so-called psi events. During the 15 years of conducting meta-analyses on parapsychological ex-

periments, the parapsychologists claim that effect sizes have remained relatively stable. However, this cannot be taken as support for the existence of psi. In a progressive science, as the research develops and the sources of error are tamed, the effect sizes should appreciably grow larger with time. Until this happens in parapsychology, the case for psi will make little headway in the scientific community.

Parenthood and Adult Psychological Developments

Extensive debate since the 1950s on the question of whether and how becoming a parent alters one's life has led to three different but not mutually exclusive answers: In terms of individual and marital functioning, the transition to parenthood produces (a) pri-

marily negative changes, (b) few significant negative or positive changes, and (c) an impetus toward psychological development. We conclude that there is truth in all three alternatives.

1. Framing the Questions: 1950–80

Erik Erikson (1959) claimed that people inevitably experience a period of disequilibrium, crisis, and intrapsychic conflict when faced with new and difficult developmental tasks (see *Erikson, Erik Homburger (1902–94)*). Crises are necessary for developmental growth. If they are not resolved, fixations, regressions, and other forms of psychological dysfunction may result. Thus, normative life transitions represent both danger and opportunity.

LeMasters (1957) interviewed 57 married couples who had become parents in the previous five years. He came to what was then a startling conclusion: 83 percent of the couples had experienced an extensive or severe marital crisis within the first year after giving birth. In response, Hobbs and his colleagues conducted a series of studies (e.g., Hobbs and Cole 1976: 728) and argued that ‘initiating parenthood may be slightly difficult, but not sufficiently difficult to warrant calling it a crisis.’

There were four main problems with virtually all studies of the transition to parenthood in the 1960s and 1970s: (a) They contained little description of what actually happens as partners became parents; (b) crisis was always described in negative terms and measured in arbitrary and inadequate ways; (c) couples not having babies were not included as a comparison group; (d) all the studies were retrospective and failed to measure change by following couples from before to after they had become parents.

2. Becoming a Family as a Major Life Transition: Research from 1980s to 2000

2.1 What Happens to Men, Women, and Marriage as Partners become Parents?

Longitudinal prospective studies designed to assess the impact of becoming parents emerged in the 1980s. Studies by Belsky and his colleagues (e.g., Belsky et al. 1989) and the authors of this article (e.g., Cowan et al. 1985) were guided by multidomain models of the family as a system (see also Heinicke 1984). Consistency over time and change in average level of function were examined in five family domains: each parent’s (a) self-concept and sense of well-being; (b) quality of relationship with their parents; (c) quality of relationship with the baby; (d) marital quality; and (e) balance of life stress and social support. Although some measures of adult functioning and life stress remain stable from late pregnancy through the first year or two of parenthood, various studies find both

quantitative and qualitative change in each of these five family domains.

New parents take on new identities and experience shifts in their self-perceptions and their role in the world. Whether or not old intrapsychic conflicts re-emerge, new parents find themselves renegotiating relationships with their parents. And now, two new family relationships take center stage—between mother and child and father and child. Friendship networks and work arrangements change for both men and women. There is consistent evidence of significant qualitative and quantitative changes in the marriages of heterosexual couples. (Longitudinal studies of gay and lesbian couples making the transition to parenthood have yet to be published.) The division of family labor becomes more traditional, with women doing more housework than they had before, and far more of the care of the children than either partner expected. Levels of marital conflict increase over time, especially about ‘who does what?’ (Cowan and Cowan 2000). Not surprisingly, then, satisfaction with marriage declines over the early childrearing years.

2.2 Is Becoming a Parent a Major Life Transition?

We describe transitions as longterm processes that result in a qualitative reorganization of both inner life and external behavior. A major life transition involves a qualitative shift from the inside looking out (how individuals understand and feel about themselves and the world) and from the outside looking in (reorganization of the individual’s or family’s personal competence, role arrangements, and relationships with significant others). Because systematic longitudinal studies find both quantitative and qualitative shifts in partners’ sense of self and relationships—within the family and with friends and co-workers—we have no hesitation in concluding that becoming a family constitutes a major life transition.

3. Does the Transition to Parenthood Elevate the Risk for Individual or Marital Distress?

3.1 Negative Change over Time

Is the disequilibrium experienced by couples becoming parents accompanied by increased levels of individual and marital distress? The evidence supports a qualified affirmative answer. For example, women are at increased risk for depression during the transition to parenthood (e.g., Campbell et al. 1992). Approximately 10 percent of women develop clinical depression serious enough to interfere with their daily functioning in the postpartum period. There are no epidemiological data documenting the incidence of postpartum depression or other psychological distress for new fathers.

Of more than 20 longitudinal studies conducted in various parts of the USA, Germany, the UK, and Israel, only three failed to find a statistically significant decline in marital satisfaction after the birth of a first child. In two of the three studies, the couples having babies had married recently, and none of the three included first-time parents in long-term marriages. While our own study included a control group of couples not having a baby and found smaller amounts of negative change in the no-baby couples over two years, after five years the childless couples had a much higher divorce rate. Thus, in the short run, the childless couples were doing well, but over time their relationships were vulnerable, often to issues concerning whether and when to have children. Although simply adding up studies with findings supporting one side or another has drawbacks, we feel relatively assured in concluding that there is a statistically significant risk that many marriages will suffer increases in conflict and declines in satisfaction in the early years of parenthood.

It is important to note that (a) these studies report group trends, (b) not all couples show a decline in marital satisfaction (about 20 percent do not), and (c) the average decline over the first year or two of parenthood is quite small. Nevertheless, because marital satisfaction tends to decline further over time, even small increases in marital conflict or dissatisfaction during the family-making period may be important markers of potential family distress.

3.2 Consistency over Time

Despite significant shifts in average level of functioning from before to after the birth of a first child in the five domains of family life assessed in studies cited here, there is remarkable consistency over time in rank order of well-being or distress in new parents. A baby's arrival is unlikely to destroy well-functioning marriages or generate closer, more satisfying relationships between already troubled partners. The high level of cross-time consistency means that even if the transition to parenthood does not elevate the risk of marital distress, when men, women, and marriage are not doing well before the baby is born, they are likely to be distressed in the early family-making years. In terms of prevention planning, these findings indicate that it is possible to identify individuals and couples who are at heightened risk for later distress and dysfunctional behavior patterns on the basis of assessments made before their babies are born.

3.3 Single Parents

Surprisingly, the transition to parenthood has not been well studied in samples described as high risk by

virtue of single parenthood, poverty, or neighborhood violence. Although preventive interventions have been offered to single mothers by home visitors (cf. Olds et al. 1998), the conception of what is needed in these interventions does not take into account that many of the high risk factors operate as additional or amplifying risks, over and above those generally associated with becoming a parent.

4. Can the Transition to Parenthood Promote Adult Development?

Given some of the negative changes and marital distress reported following the birth of a first child, it may seem surprising to ask whether becoming a parent can promote adult development. We suggest, as Erikson (1959) argued, that it is precisely this kind of stress that ultimately can lead to positive developmental change (see Erikson, Erik Homburger (1902–94); *Adult Development, Psychology of*).

Development in adulthood has sometimes been defined as passing normative family life milestones (e.g., entrance to adulthood, courtship, marriage, familymaking) or entering new developmental stages. However, there are neither invariant milestones that precede parenthood nor a convincing body of theory or research to suggest that there are hierarchically integrated stage-like organizations of cognition, personality, and relationships associated with becoming a family.

Elsewhere we have advanced an alternative view (P. Cowan 1988). At the beginning of the 1960s, Allport's functional theory of personality (1961) provided a description of maturity as a general criterion of personality development in terms of six characteristics: (a) extension of the sense of self; (b) warmth in relating to others; (c) emotional security/self-acceptance; (d) realistic perceptions and skills; (e) self-insight and humor; and (f) the establishment of a unifying philosophy of life. Change in the direction of maturity occurs when a person's level of functioning can be described as having become more differentiated, integrated, and adaptive.

We are not aware of systematic longitudinal studies of parenthood as a developmental phase or stage from any of the theoretical perspectives outlined here. Anecdotal evidence from participants in our studies of several hundred couples suggests that babies do stimulate shifts in their parents in the direction of increased maturity (see P. Cowan 1988). Most new parents describe complex changes in their identities. Others describe their relationships with their baby as having 'opened them up' to deep feelings that challenge them to become more effective problem solvers. We do not know yet whether these shifts occur together in the same person, or which factors lead some new parents to become more mature.

5. Implications for Intervention

We have been disappointed to find that few service providers and researchers have created and systematically evaluated interventions for expectant parents designed to (a) reduce or prevent the negative outcomes associated with this major life transition, and (b) increase parents' ability to maintain strong and productive family relationships. Early on, Shereshefsky and Yarrow (1973) provided individual counseling for some expectant mothers. Clulow (1982) conducted monthly meetings for expectant couples, but not in a controlled study with a no-intervention comparison group. Our own intervention (Cowan and Cowan 1999) based on random assignment to a no-intervention comparison or to groups of couples meeting weekly with mental health professionals for three months prepartum and three months postpartum had initially promising results. It staved off declines in marital satisfaction from 6 to 66 months postpartum, and all intervention couples remained in intact marriages until their children were three, while 15 percent of the no-treatment controls had separated or divorced. Because of increasing evidence that marital function plays an important role in shaping parent-child relationships and affecting children's early development (Cummings and Davies 1994), we believe that preventive interventions for partners becoming parents have the potential to promote more positive trajectories of adult development and family life quality.

6. Directions for Future Research

More research is needed to understand individual differences in pathways through the transition to parenthood and why some couples show increased satisfaction and adaptation while others decline. The question of whether and how the transition to parenthood produces development in adulthood is wide open for further research. Systematic studies of interventions to facilitate individual and couple functioning as partners become parents could provide important information for strengthening new families, at the same time testing hypotheses about the mechanisms involved in producing positive change during this major life transition.

Parenting: Attitudes and Beliefs

Parenting has been investigated extensively by developmental psychologists ever since Freud drew formal attention to its critical significance for children's social, emotional, and intellectual functioning. In studying parenting, researchers have come to believe that parents' attitudes and beliefs are centrally important in directing their treatment of children. Therefore, much effort has been focused on looking at links between how parents think about children and child rearing—both generally and in specific situations—and child outcomes. In this article, global and specific attitudes and beliefs are discussed, with an emphasis on the challenges provided by their measurement.

1. What are Attitudes and Beliefs?

Attitudes include beliefs or opinions, an evaluation of those beliefs, and an intention to act in accord with them (Ajzen and Fishbein 1980). People with a

positive attitude to exercise, for example, may reveal their positive feelings by agreeing with others who endorse the same position, by exercising more themselves, by admiring others who exercise, or by encouraging others to exercise. Thus attitudes provide a link, albeit not a perfect one, between thinking and action.

2. Global Attitudes and Beliefs

Dozens of measures of parental attitudes and beliefs have been devised, as investigators have tried to understand the relation between parents' thoughts and actions and children's resulting development. Holden and Edwards (1989) and Holden (1995) have noted the basic assumptions in this approach as well as the fact that they are sometimes violated. These include the premise that parents have pre-existing attitudes, although this is not always the case; that attitudes do not change over time, although they can certainly be modified by education and experience with children; and that parents are not ambivalent with respect to them, although they often are. When these assumptions are violated, relations between attitudes, parents' behavior, and children's development will be less robust.

2.1 Approaches and Findings

Attitudes are assessed either through interviews or questionnaires, with the latter more frequently employed. The majority of attitude questionnaires have focused on parents' views about different child-rearing practices, with a smaller number addressing views of children (Holden 1995). Questionnaires addressing ideas about child-rearing practices have focused on two major features: the quality of the parent's relationship with the child and the extent to which the parent attempts to control the child's behavior. Questions therefore deal with issues of warmth, acceptance, responsiveness, coldness, rejection, and hostility on the one hand, and permissiveness, firm control, punitiveness, and restrictiveness on the other. Typical statements, with which parents indicate their degree of agreement or disagreement, are: 'Children should always treat adults with respect' and 'I enjoy being with my child.'

Researchers have looked at relations between these attitudes and a variety of features of children's development. Positive attitudes toward warmth and reasonable firm control are moderately predictive of outcomes such as high academic achievement, high self-esteem, and a strong moral orientation, while endorsement of restrictiveness and lack of acceptance relate moderately to negative outcomes (Maccoby and Martin 1983). It should be noted that most of the research has been conducted with Anglo-European middle-class mothers and their children and that it is

not clear the same pattern of relations holds for lower socioeconomic classes, in other cultural contexts, or with fathers (Parke and Buriel 1998).

2.2 Limitations of Questionnaire Measures and Needed Improvements

Although the assessment of parenting attitudes has provided useful information for developmental psychologists, dissatisfaction with modest relations between attitudes and child outcomes has fostered attempts to improve existing approaches (Holden 1995). For example, investigators have begun to show a greater concern with the actual relation between attitudes and behavior. Given the basic assumption that attitudes inform behavior, and that it is parenting behavior that determines children's development, there is, of course, little use in studying attitudes if they do not reliably reveal themselves in parenting actions. Reasonable attitude-behavior links are more likely to be found when items assessing attitudes on questionnaires match the nature of the parent's action, e.g., the response to a question about the importance of firmness in getting children to obey is related to observations of reactions when a child fails to comply with a parental request. As well, links are stronger when many examples are added together to provide an aggregated measure of a particular parenting behavior. The fact that relations between attitudes and behavior are stronger under these two conditions underlines two things: asking about general attitudes may give incomplete information when it comes to specific actions, and parenting behavior varies across situations and is determined by a number of variables so that a variety of situations needs to be assessed in order to gain an accurate impression of a particular parent's attitudes.

Holden and Edwards (1989) have raised other methodological concerns. For example, statements on questionnaires are often couched in the third person on the assumption that this may lead to more valid answers because respondents are not placing themselves in a negative light. On the other hand, this approach produces situations in which respondents are not sure whether they are to answer with respect to what might be ideal attitudes rather than what they know to be their own attitudes. Another problem is that attitude measures are based on self-report data that depends on the willingness of the respondent to be honest or even to have access to or conscious awareness of a particular attitude. Psychologists have become increasingly aware that much behavior is determined by implicit or automatic processes, and a variety of techniques have been developed to study the operation of these processes (Bugental and Goodnow 1998). Clearly, however, asking people to state their position on a given topic is not going to be effective if that position is unavailable to conscious introspection.

3. Parental Thinking in Specific Situations

One response to the problems of measuring global attitudes has been to focus on the thoughts or beliefs parents have when they are interacting with their children in specific situations. Thus, rather than ask about general and abstract beliefs and attitudes, researchers have asked about the content of parents' thinking in a particular context. For example, as noted above, inquiries about global attitudes have focused on parents' beliefs about the best child-rearing practices, e.g., authoritarianism, or the extent to which children should obey their parents. More recent inquiries focus on goals, such as obedience, that parents have in a particular situation. Thus the interest in general attitudes has been translated into an interest in goals at a particular point in time, with the recognition that goals of a parent change as a function of context (although, on average, some people may be more inclined to favor some goals more than others). Hastings and Grusec (1998) have shown that, when a child misbehaves, many parents have obedience as their goal and they are punitive. If all one knew was the extent to which those parents had endorsed a general measure of authoritarianism without knowing their specific goal, prediction of their actual behavior would be less accurate.

The study of particular goals reflects the interest of developmental researchers in attitudes toward child-rearing practices. However, interest in parenting cognitions has expanded to a wider range of content including theories about how children develop, expectations about children's abilities, and feelings of self-efficacy with respect to parenting. In the next three sections three additional areas that have received considerable attention will be described.

3.1 Causal Attributions

Parents try to find explanations for why their children have behaved in a particular way, that is, they make 'causal attributions.' Although people make causal attributions in a variety of contexts, parents are probably particularly likely to make them because they need to understand their children so that they can effectively influence them. Dix and Grusec (1985) have outlined some of the features of parents' thinking in this context. In the search for explanation, parents can make internal or dispositional attributions that find the source of action in the child's personality or character. Alternatively, they can make external attributions that locate the source of action in the external situation or environment. When a negative action is attributed to dispositional factors it is most often seen as intentional and under the child's control. In this case parents have been shown to react punitively, possibly both because of their accompanying anger and because a Western ethical system dictates that intentional misdeeds should be punished. Parents who

make external attributions, believing their child was tired or provoked or did not know any better, are likely to respond in a more benign way, e.g., by reasoning in an attempt to guide their child's future actions. When the attributions are accurate, parental behavior is likely to be appropriate for modifying the child's actions. When the attribution is inaccurate, however, parenting will be ineffective, given that children who lack knowledge, for example, are merely punished and do not learn what correct actions are, or children who have knowledge do not experience the negative consequences of their actions.

3.2 Relative Control

The impact of parental thinking has also been mapped in the domain of perceptions of relative control between parents and children. In her research program, Bugental (Bugental 1992, Bugental and Goodnow 1998) has shown how parents' beliefs about such control are elicited in difficult interactions with their children. Once elicited, these beliefs have an impact on emotional reactions, behavior, and, subsequently, child outcomes. Parents who perceive their children as having more control of the difficult situation than they do experience physiological arousal that reflects feelings of threat aroused by the apparent reversal of power. Because they feel relatively powerless they resort to coercive and overly aggressive behavior. At the same time they transmit confusing and inconsistent messages to the child, both because their cognitive capacity is limited by the distracting thoughts associated with threat and because they cannot adequately inhibit the negative feelings they are experiencing. In turn, the confusing behavior leads to nonresponsiveness on the child's part that serves to reinforce the parents' negative thoughts and affect.

3.3 Attachment Relationships

Early in their development children learn that their needs for security will either be dealt with satisfactorily, rejected, or responded to inconsistently (Ainsworth et al. 1978) (e.g., see *Attachment Theory: Psychological*). These early experiences form the basis of adult working models of relationships that function throughout the life course and that manifest themselves in parenting behaviors. Thus adults who are secure with respect to the satisfaction of their emotional needs have a model of relationships that enables them to respond sensitively and supportively to their children. Adults whose model includes others as rejecting are cool, remote, and task-focused in their interactions with children, while those with models of other as inconsistent are unpredictable and confusing in their parenting actions (Crowell and Feldman 1991).

4. Automatic vs. Conscious Thinking

The earlier discussion of global attitudes noted that some of these attitudes are not open to conscious awareness. The same distinction has been made in the area of parenting cognitions, with some thoughts seen as automatic and implicit and others as more open to conscious reflection and awareness. Bugental has argued, for example, that the experience of a difficult child activates a high threat schema that operates at a preconscious level and places parents in a state of perceptual readiness to react to certain events in the environment. Thus the stress produced by a problematic interaction with a child is filtered through this schema, which in turn influences both emotional feelings and more conscious or deliberate ideation. Mental representations of childhood attachment experiences are also considered to operate outside conscious awareness (Bretherton 1985). Parents' goals and attributions about children's behavior may be more open to conscious awareness and reflection—they frequently change in response to changes in the external situation. On the other hand, some parents are not able to use situational information to change their attributions for child misbehavior (Milner and Foody 1994), an indication that even the same kinds of cognitions may be sometimes more and sometimes less automatic.

5. Future Directions

The use of global parenting attitudes and beliefs and specific cognitions to understand parent-child relationships will continue to be a significant part of the arsenal of developmental researchers. Measurement issues remain of paramount importance. Strong linkages between measured attitudes and behavior still need to be demonstrated. A fundamental question has to do with how to measure attitudes and beliefs that are automatic in nature and, as such, cannot easily be articulated by respondents even if they are perfectly willing to be open and honest in their answers. The move must be away from straightforward transparent questions to more subtle measures where 'correct' or socially acceptable answers are not so self-evident. Bugental's measure of relative control (Bugental 1992) and the Adult Attachment Interview which assesses mental representations of attachment relationships (Main and Goldwyn 1991) are examples of such measures, and they have proved to be accurate predictors of a variety of parenting behaviors and child outcomes. Another important question has to do with the origins of various parenting belief systems. Some presumably are part of the cultural context in which parents find themselves. Others come from experience with one's own children. And others emerge as a result of a parent's own experiences as a child; it is these latter, presumably, that are most automatic and most difficult to alter when alteration seems desirable.

Finally, linkages among the many sets of beliefs that have taken up the attention of researchers need to be made, as well as explorations of the distinctive ways in which each contributes to the parenting process.

Parenting in Ethnic Minority Families: United States

'Parenting' refers to the training or raising of children, focusing on parents' responsibility to guide children's development toward behaviors determined as functional in the surrounding culture. Parenting practices are shaped by the contextual circumstances in which the parenting occurs. One such contextual circumstance is ethnic minority status. Ethnic minority status in the USA usually refers to people of color, those with physical characteristics differentiating them from the majority white American. Ethnic minority groups include African Americans, Asian Americans, Mexican Americans, and American Indians. The implications of ethnic minority status have been influenced greatly by the difficulties such designated groups have experienced in attempting to integrate and assimilate into the mainstream of US society.

Past conditions of involuntary immigration and slavery, legal discrimination and segregation, exclusion and restrictions, and forced removal and internment to reservations have influenced the attitudes, perceptions, and behavioral patterns of the respective ethnic minorities. Interestingly, it does not matter whether ethnic minority groups were volunteer or forced immigrants or whether they were an indigenous people, their historical struggles of assimilating into US society was qualitatively different from other noncolor ethnic Americans (Ogbu 1981, Wilson 1989). This entry considers the evolved parenting practices of the four ethnic American groups, focusing on African-American, Chinese-American, Mexican-American, and American Indian practices, illustrating their marked distinction from the dominant culture as well as variations between the ethnic groups.

1. Parenting Behaviors and Minority Families

Historically, past research on parenting has described practices in minority families in terms of their contrast to practices of the majority. In comparisons, dominant cultural norms and values have been used to evaluate the practices of minority parents, deeming them changeworthy. Comparing practices of ethnic minorities with those of the majority remains an important topic given the stigma and social implications such comparisons elicit for ethnic minorities in the USA. Closer examination of parenting in each minority group suggests a link between the differing historical experiences of the groups and their evolved parenting practices. Analyses of adolescent adjustment indicate the adaptive nature and functionality of parenting among ethnic minorities.

Two basic parental behaviors, warmth and control, presume to underlie most categories of parenting practices. Baumrind (1991) formed four patterns of

parental authority based on differing levels of parental warmth and control. The patterns emerging from Baumrind's studies were authoritarianism, authoritativeness, permissiveness, and neglectful/rejecting. Authoritarian parents displayed high levels of parental control but low levels of warmth. Authoritative parents were high in both parental warmth and control. Permissive parents were highly responsive (i.e., warm) to their children, but did not place many demands (i.e., control) on them (Baumrind 1991). Neglectful/rejecting parents were low in both parental control and warmth.

Because authoritarian, authoritative, and permissive parenting represent a central concern of this entry, additional comments are warranted. Specifically, authoritarian parents are described as using absolute standards in order to shape and control the attitudes and behaviors of their children. They place high regard on such values as respect for authority, hard work, and maintenance of order; simply put, the parents' word is not to be questioned. Authoritative parents are best described as applying firm parental authority while engaging in and encouraging parent-child interaction with respect to socialization. Further, authoritative parents address their child's affective needs. Permissive parents do not maintain and enforce clear behavioral expectations but are highly attentive to the child's affective needs (Baumrind 1991).

Since parenting practices are assumed to be flexible and contextually sensitive to situational demands, comparative claims will not be offered regarding the advantages of any parenting style. Parents presumably incorporate their own beliefs about how the world works into their child-rearing practices. Such beliefs, developed by parental experiences, naturally have some bearing on what parents believe their children are likely to face in their own lives. Hence, a basis of understanding parenting practices is the notion that many contextual differences will shape the child-rearing practices. Each parenting style is manifested in attitudinal and behavioral attributes that vary both between different ethnic groups and within ethnic groups (see *Cultural Variations in Interpersonal Relationships*).

2. Socialization in African-American Families

Wilson (1989) asserts that an important social context of African-American family development involves the involuntary migration to the Americas followed by a protracted period of African-American enslavement and, after emancipation, segregation and inferior status base on race and struggle for civil rights and political freedom. The African-American family evolved into an extensive familial structure that was based on mutual support and obligation.

Two types of studies have explored the child-rearing practices common to African-Americans. Compara-

tive studies have focused on the differences between African-American child-rearing practices and those common to other ethnic groups (Rickel et al. 1988, Baumrind 1991, Bartz and Levine 1978), whereas within-group approaches focus on the variance in child-rearing practices among African-Americans only (Hill 1995, Kelley et al. 1993, Luster and McAdoo 1994). Much of the comparative research on parenting describes African-American parenting in terms of its relation to the dominant group's child-rearing practices and ideals (e.g., Baumrind 1991). In contrast, the within-group research has described the diversity of attributes and behaviors within African-American families (see *Socialization in Adolescence*).

Comparative studies on socialization have generally found African-American parenting styles to be authoritarian and more restrictive than European-American styles (Baumrind 1991, Rickel et al. 1988, Kelley et al. 1993). Also, African-American parents appear to employ gender-specific socialization practices. Specifically, African-American boys are more likely to be expected to act maturely and responsibly than are European-American boys. Parents of African-American girls have been shown to exert high levels of control. African-American fathers discourage infantile behaviors in their daughters. African-American mothers display firm enforcement and rejecting behaviors, and discourage nonconformity in their daughters (see *Poverty and Child Development*).

Bartz and Levine (1978) examined specific parenting practices in low-income African-American, European-American, and Mexican-American families. African-American parents exercised more control over their child's behavior, were more likely to press for acceleration of development, were more concerned about their children wasting time, and used supportive behaviors more frequently than European-American and Mexican-American parents. African-American parents also reported doing more to enforce their rules and expectations. Generally, African-American parents value strictness and expect their children to gain a sense of responsibility. They encouraged decision making, expressed loving concern, and closely monitored their children's behavior to assure goals such as obedience and high achievement (Bartz and Levine 1978).

Within-group ethnic studies generally focus on the specific characteristics that influence the development of a particular parenting style (Kelley et al. 1993). Generally, it has been found that mothers with a higher family income and a greater number of children report using more parental warmth and firm discipline and lower levels of control. In addition, discipline has been shown to correlate negatively to the number of adults in a family (Wilson 1989).

Inasmuch as authoritarian practices appear to be common among African-American families, there are important familial caveats that are related to familial socioeconomic levels, maternal resources, and neigh-

borhood. Namely, older, educated, middle-class, married mothers employed more authoritative practices than do young, single mothers with less education. Conversely, young, single, less educated mothers were more likely to emphasize obedience, use physical punishment, and employ a more parent-oriented approach (Kelley et al. 1993). Also, mothers who perceived their neighborhoods as dangerous were likely to use harsh discipline and authoritarian practices.

In addition, Luster and McAdoo (1994) found that adolescents with the highest level of cognitive competence came from homes with older, more educated and high esteem mothers, a supportive environment, and a small family size. Thus, there is variance of socialization practices among African-American families.

3. *Socialization in Chinese-American Families*

Research on Chinese-American parenting practices is often described in ways similar to the characteristics of the authoritarian style. However, the child-rearing practices may be the outgrowth of the Chinese philosophy of hsaio, or filial piety, which prescribes Chinese children to fulfill the desires of their parents (Lin and Liu 1993, Kelley and Tseng 1992, Chiu 1987). Devotion to one's parents takes precedence over other relationships, including one's obligation to one's own children (Lin and Liu 1993). Parents are very involved in the training of their children, and hold a definite position of authority over them. Strict discipline is highly valued. Parental control, therefore, is apparent as children learn that their parents are 'always right' (Chiu 1987, Kelley and Tseng 1992, Lin and Liu 1993).

Kelley and Tseng (1992) examined the child-rearing practices of Chinese-American and European-American mothers. Specifically, they measured use of external threats and punishment, permissiveness, and emphasis on school-related skills, obedience, concern for others, and self-reliance. Chinese-American mothers scored higher than did European-American mothers on ratings of restrictiveness and control (Chiu 1987, Kelley and Tseng 1992).

4. *Socialization in Mexican-American Families*

Mexican Americans make up the vast majority of Latino peoples living in the USA. Other groups include Central and South Americans, Puerto Ricans and Cuban Americans. Mexican Americans have been incorporated in US society through military conquest of the Southwest and ambivalent immigration policies that at some times encourage immigration and at other times deports citizens of Mexican decent. Bartz and Levine (1978) found Mexican-American parents to exhibit more authoritative behaviors than African-

American parents but less authoritative behaviors than European-American parents. Specifically, Mexican-American parents' reported levels of firm control and warmth were intermediate between those reported by African-American and European-American parents. In examination of Mexican-American and European-American mothers from low and high socioeconomic status (SES), Cardona et al. (2000) indicated that Mexican-American and higher SES mothers reported using higher levels of discipline and lower levels of nurturing behaviors than did European-American and lower SES mothers. Moreover, higher SES Mexican-American mothers reported more frequent use of discipline than did other mothers. Further, Buriel (1997) found generational patterns in the Mexican-American parents of first-, second- and third-generational children. Parents of first- and second-generation children reported authoritative-oriented practices whereas the parents of third-generation children reported authoritarian practices. In addition parents of first- and second-generation children reported higher level of parental permissiveness than did the parents of third generation children. Taken together, it would appear that as Mexican-American parents become more acculturated and integrated into US society, they resort to more authoritarian patterns of parenting.

5. Socialization in American Indian Families

Although American Indians are a diverse group making up 450 distinct groups, one common experience shared by the diverse groups is their history of military conflicts with white Americans and forced removal from the ancestral homelands and placement on reservation. American Indian customs place great value on collectivism, natural harmony, humility, and respect for and importance of family. Because the family network is an important part of American Indian life, child rearing is a shared activity among the network. Through valued collectivism and the family support network, the growing child is placed in the protected environment of close relationship with familial kin (Forehand and Kotchick 1996). Several researchers have indicated that specific parenting practices among American Indians appear permissive in that American Indians report using low levels of control or punishment and high levels of warmth (Cross 1986, Red Horse 1997).

6. Socialization of Children and Adolescents in the Context of Ethnic Differences

Although research maintains that authoritative parenting produces the most optimal child outcomes (Baumrind 1991), numerous studies suggest that the actual positive effects of authoritative practices are correlated with some specific domains of development

only (Steinberg et al. 1995) and are generally more relevant to European-American adolescents than ethnic minority adolescents (Steinberg et al. 1995, Darling and Steinberg 1993) (see *Parenting: Attitudes and Beliefs*).

The differential cultural and contextual experiences of ethnic minority groups are likely to provide an explanation for the differing effects of the authoritarian style on child outcome between ethnic minorities and the majority group. Although authoritarian parenting practices among European-American parents may be viewed as excessively harsh and punitive, and may be indicative of parental rejection and lower level of investment, similar practices among African-Americans may be interpreted as a sign of parental involvement and concern (McLeod et al. 1994). African-American mothers report using authoritarian measures to teach their children about harsh realities in a racist society (McLeod et al. 1994, Hill 1995), for teaching values such as respect, child safety, and school achievement (Kelley et al. 1993), and as a protective measure in high-risk environments (Rickel et al. 1988).

Chao (1994) suggests that Chinese-American parents' use of authoritarian and restrictive practices are more indicative of parental concern, involvement, and caring than parental hostility and aggression. Authoritarian practices are part and parcel of successful and harmonious family and community life (see *Cultural Psychology*).

7. Concluding Remarks and Future Directions

Several implications of the review on minority families' socialization practices are evident. First, although the concept of authoritarianism is generally analogous to parental hostility, aggression, and dominance, the common occurrence of authoritarian and restrictive parenting practices in African-American, Chinese-American, and Mexican-American populations are not necessarily associated with such negative parental attributes. Rather, the use of authoritarian procedures has demonstrated functional benefits for ethnic minority Americans. Second, although common among several of the ethnic minority American groups, the authoritarian and restrictive practices evolved from different contextual concerns. For African Americans, the use of authoritarian practices were developed and maintained in response to harsh environmental realities like low-income, inner-city living environments, and hostile discriminatory practices of US society. For Chinese Americans, traditional cultural beliefs and values of filial piety initiated the practices. For Mexican Americans, value of the strong patriarchal presence in families appears to increase the use of authoritarian practices. Interestingly, American Indian socialization practices are typically permissive, while close-kin networks maintain protectiveness. Last, different parenting practices do have different

meanings, uses, and benefits for minority and majority children (Chiu 1987, Ogbu 1981). Contending that one method embodies positive outcomes for one group does not imply that another group would or would not benefit from that practice. Parenting practices must be examined carefully from the perspective of the people who employ them and the contexts in which those practices will be employed. In order to understand ethnic minority socialization, it is important to examine applied socialization practices within their particular ecological context (see *Socialization, Sociology of*).

It is clear that the US population will continue its racial and cultural diversification. Likewise it is acceded that a diverse US population will display different kinds of socialization practices. Contextual aspects of socialization will continue to play a fundamental role in understanding and determining adaptive socialization processes. Thus, socialization practices must be appreciated for their particular situational meaning, significance, and consequence. Rather than presume peremptory negative and positive connotations of authoritative and authoritarian parenting practices, the merits of each style should be judged according to its contextual contingencies and influence on adolescent adjustment. Also, it is important that we view socialization practices from a cultural perspective. An understanding of the interacting mechanism of culture, family, and socialization may lead to an appreciation of the familial complexities experienced by various ethnic groups. Furthermore, understanding the links between ethnic minority status, socialization practices, and child outcomes may foster appropriately directed family interventions.

M. N. Wilson and M. D'Amico

Parents and Teachers as Partners in Education

Parents have always been involved in children's preparation for adulthood, but during the twentieth century many responsibilities were taken over by schools. In Western societies a model of teachers and parents as 'partners in education' gradually evolved which currently enjoys widespread academic and political support. In the contemporary climate of globalization it may well be presented as the ideal for

all societies with mass education systems. Yet critics claim it is difficult to implement at best, and may easily serve further to disempower socially disadvantaged sectors of the population.

1. *Evolution of the Partnership Model*

In any society, economic, sociocultural, and political conditions, as well as pedagogical theory, help define the preferred model of home-school relations.

1.1 *Historical Shifts*

During the early decades of mass schooling in Western societies, as teaching methods became more specialized and when teachers were among the most highly educated members of their communities, parents were viewed as ill-equipped to understand what happened in classrooms and liable to do more harm than good if they interfered. In the more widespread affluence of the post-World War II period, parents came under much greater pressure to assist by providing a materially enriched home environment, but were only expected to become significantly engaged in discussion of their child's education if schools identified problems. Parents were not regularly invited beyond the school gate until the 1970s; opportunities were then limited initially to formal discussions about children's progress, or provision of unskilled assistance to teachers, but gradually expanded to include more responsible duties in classrooms and more freedom to engage informally with staff. By the late 1980s research proclaimed major parental involvement *as educators* to be essential to children's success in school, and parents themselves were demanding more say in educational decision-making.

1.2 *Contemporary Partnership Programs*

The language used to strategize home-school connections has reflected these shifts. Current policies espousing 'partnership' have implications that distinguish them in important ways from those based primarily on parental 'involvement' or 'consultation.' The partnership paradigm requires consensus between teachers and parents on the goals and processes of education, and implies a full sharing of information, skills, decision-making, and accountability.

Early partnership programs were typically the initiatives of individual school principals, but their establishment is now commonly assisted by research-based and/or organizational support. In a large-scale project in New Zealand, for example, experienced senior teachers were imported into schools as 'developers' to support and legitimate innovative practice and constructively challenge institutional resistance to

collaborative ways of working (Ramsay et al. 1993). In the USA, the Center for Social Organization of Schools has theorized an extended partnership framework including other family members and the wider community (Epstein et al. 1997). Implementation involves exploring opportunities for six types of engagement: *parenting* (assisting families with childrearing and establishing home environments conducive to learning); *communicating* (developing channels for reporting student progress and school news); *volunteering* (improving involvement of families as volunteers and audiences to support students); *learning at home* (assisting all parents to help children with homework and other curriculum-linked activities); *decision-making* (including families in school governance as well as Parent-Teacher Associations and other committees); *collaborating with the community* (linking students and families with other community agencies, and providing services to the community). This model promotes 'school-like families' and 'family-like schools': parents are expected to reinforce the importance of school, and schools to recognize each child's individuality.

It is recognized that program implementation is often problematic within educational systems that have traditionally operated in a very hierarchical manner. Research suggests that projects are relatively easily established when children are most dependent (of preschool age or with special educational needs) but still difficult to operate successfully in high schools, even though it is now strongly argued that parental participation remains crucial at this level. It is widely reported that training programs continue to pay insufficient attention to preparing teachers and administrators to work in new ways with families (including dealing with attendant challenges to their professional status), and that even the best-planned initiatives rarely fulfill all criteria of partnership or manage to attract all families.

2. *Critique of the Partnership Model*

Despite acknowledged implementation difficulties, the literature nonetheless generally supports the view that 'partnership' remains the ideal to be pursued. However, some repeatedly articulated misgivings critique this premise.

2.1 *Research Support*

Some writers contend that research has *not* provided compelling support for the core claim that the impact of parental involvement is positive, that too much of the corroborative evidence comes from studies of self-selected samples of schools and parents, and that assumptions about the *direction* of causal connections between involvement and children's success have been

insufficiently interrogated. It is also argued that researchers have failed to investigate seriously some of the potentially *negative* consequences, for example, the impact of highly engaged parents whose motivation may be rooted in an antischool stance, the 'dark side' to the intense involvement of some ambitious or 'pushy' middle-class parents, and the risks associated with seeing increased parental participation as the universal panacea for schools' pedagogical or financial problems. Possibly there has been a 'conspiracy' to avoid examining the new buzzword of partnership too closely in case it fell apart (Bastiani 1993).

2.2 Partnerships and Power Relations

Whereas partnership protagonists such as Epstein argue that parents are more concerned about 'information,' 'communication,' and 'participation' than about 'power' or 'control,' others claim the language of collaboration and partnership helps to silence the naming of important power asymmetries in home-school relations. 'Participation' may therefore mean that parents play a more active role, but are given no genuine opportunity to challenge the school's authority to define the nature of that role (Fine 1993). It may deflect attention from gender disparities, such as mothers' under-representation in positions of governance or schools' reported reluctance to utilize fathers in classroom support roles.

Furthermore, parents and teachers do not necessarily mean the same thing when they use terms such as 'helping children succeed.' Discussing the enduring documentation of socioeconomic class (SES) differences in parental involvement, Lareau (Lareau 1989, Lareau and Horvat 1999) suggests that these differences have several roots, including the fact that whereas middle-class parents typically embrace opportunities to scrutinize and question school practices, low-SES parents often prefer a relationship characterized by *separateness*, expecting teachers to do their job and seeing themselves as helping best by deferring to professional expertise. Her analysis also incorporates Bourdieu's (1990) notion of *cultural capital*: high-SES children enter schools with more cultural capital potentially available for activation because schools tend to use the linguistic structures, authority patterns, and types of curricula with which they are more familiar. There may be negative consequences for parents' dignity and authority in the home if they cannot (or prefer not to) perform their designated roles as educators in accordance with these terms (see *School Achievement: Cognitive and Motivational Determinants*). Low-SES parents may feel less confident or comfortable visiting schools, and may have more reason than high-SES parents to fear that closer links with schools could result in greater family surveillance by government agencies. Middle-class domination of that aspect of 'partnership' quintessentially disting-

uishing it from other models—involvement of parents in all aspects of school governance—may function to sustain rather than challenge societal inequalities. While some projects work hard to minimize such impediments, or avoid them through being established in more economically homogeneous communities, the generic Western model arguably privileges the ways in which *well-educated* parents wish to, and can, engage with schools.

Most of these concerns have also been addressed with reference to multiculturalism, neocolonialism, and racism (e.g., Ramsay et al. 1993, Limerick and Nielsen 1994, Lareau and Horvat 1999) (see *Minorities; Multicultural Education*). Whether or not imbalances of power or influence fundamentally violate the spirit of partnership remains a key feature of current debate.

2.3 Political Intervention

In Western societies, partnership models enjoy widespread political support, provoking debate about the extent to which schools should be legally mandated to develop partnership programs and parents required to participate. Legislation might be the only way to reduce significantly existing societal inequalities *or* it could equally well serve to consolidate or amplify them. Partnership initiatives may be compromised by the effects of other political interventions in education, such as imposition of a 'market model' that positions parents as selfish 'consumers' of school services. Moreover, no less than other paradigms, the partnership model should be recognized as offering national or local governments opportunities to absolve themselves from the responsibilities of maintaining struggling public school systems (Fine 1993). While the market model seeks to lay blame primarily at the door of schools, the 'family-is-school' approach could arguably enable school failure to be more easily read as *family* failure.

3. Future Trends

To some extent, future developments will be driven by research findings that resolve the implementation problems outlined above. They will also be influenced by how communities prioritize their objectives. While the pre-eminent objective may continue to be enhancement of parents' ability to promote their own children's school success (however defined), some communities or cultures may prefer a more collective approach that encourages all adults to work on behalf of all children. Other programs may focus less exclusively on children, and place more emphasis on helping parents improve their quality of life and on the broader rejuvenation of community spirit. If educational resources are limited, families may play a critical role in the development of curriculum

materials; in nations where the legacy of colonialism still positions schools as somewhat alien institutions, schemes may be focused on integrating schools more fully into the society. Whatever the objectives, a partnership ideology suggests that programs are most likely to succeed when goals are clearly articulated and informed consensus has been reached regarding the strategies employed to achieve them. As always, however, developments will be directly or indirectly influenced by external factors such as funding support and other aspects of government policy.

'Partnership' is clearly the current model of choice for white Western middle-class communities, and has many features with the potential to inform good educational practice in a wide variety of cultural settings. Nevertheless, certain conditions must be met in order that partnership programs offer all families an equitable chance of reaping the rewards of participation. Furthermore, inasmuch as technological advances may mean that children in future spend much less time either physically located in schools or pedagogically locked into the programs of individual education systems, current ideas about 'consumers,' 'providers,' and 'partnerships' may possibly soon require radical re-examination.

M. A. Payne

Pareto, Vilfredo (1848–1923)

1. Life

Fritz Wilfried Pareto was born on July 15, 1848 in Paris, France, the son of an Italian political émigré, Raffaele Pareto (1812–82). Raffaele's father, Raffaele Benedetto Pareto (1768–1831), had been made a marchese di Parigi—or, as some have claimed, even a pair de France—by Napoleon, in recognition of his collaboration in erecting the Cisalpine Republic. The Pareto family was rooted in the trade bourgeoisie of Genoa, Italy, where it had been registered in the *Libro d'oro*.

In addition to her son, whose given name was Italianized and shortened to Vilfredo, Pareto's mother, Marie Métenier (1816–89), also had two daughters. Due to a political amnesty granted by the House of Savoy, probably as early as 1858, the Pareto family was eventually able to move back to Italy. Pareto's father started to work as a French instructor for Genoa's *Scuola di Marina*. Vilfredo attended the same school, the beginning of his Italian education. When, later, Pareto's father was offered a better position in Turin, Vilfredo followed him to the capital of the kingdom of Savoy. Here, in 1867, Vilfredo received his *Licenza in scienze matematiche e fisiche*.

He then enrolled at the *Scuola di Applicazione per Ingeneri*, where, in 1870, he received his doctorate. Much later, Pareto still considered his dissertation—on 'Principi fondamentali della teoria di elasticità dei corpi solidi'—important enough to include it in his *Collected Essays on Economic Theory*. He began his professional career in Florence, working for the *Centrale della S. A. delle Strade Ferrate Romane*. From there, he went on to a management position with the *Società dell'Industria di Ferro*, traveling widely in Germany, Austria, France, England, and Switzerland.

His career left him with a sound knowledge of practical business matters. In 1882, the year his father died, Pareto chose professional retirement and settled in Florence. At around this time, he made an unsuccessful attempt at running for political office on a platform promoting his ideal of a liberal market economy. Pareto became resolved to dedicate his remaining life to his scientific pursuits. He joined Italy's oldest learned society, the highly respected *R. Accademia Economico-Agraria*. He also became a member of a second society, *Adamo Smith*, where he gave several lectures on scholarly topics and economic policy, which he also published. Moving in the upper-class circles of Florence—which then exerted a leading cultural influence throughout Italy—Pareto made a number of influential friends: the Lord Mayor Peruzzi and his wife; the politician S. Sonnino; P. Villari, who wrote a famous biography of Machiavelli; Colli, the author of *Pinocchio*; the anthropologist Mantegazza; such renowned philologists as D. Comparetti, A.

Franchetti, and A. Linaker, as well as several others. It was at this time that he married Alessandra (Dina) Bakounine (1860–1940), a Russian (no relation to the anarchist of the same name).

When Pareto met Italy's leading economist, Maffeo Pantaleoni, they soon became friends. Pantaleoni supported Pareto, as a successor had to be appointed for the Lausanne University chair held by Léon Walras, who had had to vacate his position due to his worsening mental illness. As an academic teacher, Pareto had considerable success. However, he soon asked to be relieved of his teaching duties. An unexpected inheritance set him free to concentrate on his preference for research and scholarship. Pareto's *Feste Giubilari* was published in 1917 to great critical acclaim. While this represented a personal triumph for him, Pareto continued to view himself as a victim of Italy's politicians and the *Camorra universitaria italiana*. When the Fascists took over Italy's government, various honors were offered to him; he either declined them explicitly or did not respond to them at all.

Only once did Pareto return to Italy and then only because he was forced to visit the Rome family record registration office in person. To get a divorce and be able to remarry, he needed his birth certificate. Dina, his first wife, had left him. In the summer of 1923, he married Jeanne (Jane) Régis (1879–1948), his second wife. He had met her through a newspaper advertisement in Paris. When Pareto died two months later, on August 23, 1923, he no longer possessed an Italian passport. To be able to marry Jane, he had been forced to turn in his passport at the Republic of Fiume. Conforming to his last wishes, he was buried in Céligny, his last place of residence, in a modest grave listing only the years of his birth and death and his *nom de guerre*.

2. Works

From his beginnings as a researcher, Pareto placed immense importance on the question of method. He had named his approach the logical-empirical method. In his *Manuale d'economia politica* (1994), first published in 1906, he devoted no less than 55 paragraphs to it. In his *Trattato di sociologia generale* (1983), that number rose to 144 paragraphs. 'My only intention,' Pareto wrote, 'is to describe facts and to draw logical conclusions from them' (Pareto 1983, 55). Facts were to be weighted according to relevance, not quantity. Facts based on experience were considered valid only 'as far as experience does not contradict observation' (Pareto 1983, 6).

Pareto considered this method applicable not only to the field of economics but to the social sciences as well and—implicitly or explicitly—to every field of scholarship (Pareto 1994, Vol. 1, 14). However, every inductive approach will always contain an implicit

assumption. In the sciences, this would be the supposedly homogeneous character underlying all of nature. Thus, Pareto's 'survey' is strongly similar to J. A. Schumpeter's concept of 'vision.' According to Pareto, it is quite feasible to differentiate between economic and social phenomena initially. To regard them separately does not violate the dictates of empiricism. But 'both parts then have to be integrated with each other. Only a full view of the whole thing possesses any empirical reality' (Pareto 1994).

At the heart of Pareto's *Cours d'économie politique* lies his theory of economic equilibrium. He refers to two sets of mathematical equations to describe two 'economic systems.' One system applies to barter and exchange, the other to production. If combined, both sets of equations attain validity only in a state of equilibrium (Pareto 1994, App. 131–3). 'The most interesting case,' according to Pareto, is described as a situation where the number of equations is less than the unknowns contained in the equations: 'The system is then flexible and can balance itself' (Pareto 1994, App. 131–3). 'Mathematics,' Pareto insisted, 'should be used only if it allows for an expression of certain relations between facts which otherwise could not have been expressed or which could not have been formulated using standard language' (Pareto, 559, n. 4, cf. Pareto 1983, 1732).

To describe different states of economic equilibrium, Pareto coined two terms: *ophelemité* and *utilité*. When Irving Fisher wrote a review of Pareto's work, Pareto tried in vain to discourage Fisher from confusing his terms with the terminology of Walras and Edgeworth. Fisher, Pareto argued, did not understand enough French and even misunderstood some of Pareto's mathematics (Pareto 1960, Vol. 3, p. 408).

In 1902–3, Pareto published the two volumes of *Les systèmes socialistes*, an incisive analysis of historical and present-day socialist theories, including a discussion of Werner Sombart (he had treated Karl Blücher in a similar way in his earlier *Cours*). He paid due reverence to Karl Marx as a sociologist. Economically, however, he did not give Marx much credit. Theoretically, a socialist economy might be able to solve its problems as well as any nonsocialist economy. Earlier, Pareto had already integrated socialist society and collective capital with his overall theory of economics (Pareto, Vol. 2, 714–24). Indeed, his followers, E. Barone and O. Lange, later based their own socialist theories of economics on this insight. Pareto argued against socialism not on economical but on social and anthropological grounds. He concluded that all socialist systems were eventually based on untenable social and anthropological contradictions.

In his *Manuale d'economia politica* (1994), Pareto presented a reworked version of his theory of economics with special emphasis on the various states of economic equilibrium. Typically, he differentiated between them in his famous dictum:

We can say that the members of a community, in a certain situation, enjoy the optimum of *ophelemité* if it has become impossible to distance oneself from this situation even to a small degree without benefit or damage to all members of this community; even the smallest step then necessary leads to profit for some members of the community or loss for others (Pareto 1994, 33).

This concept has been named the Pareto optimum. Later, it served as the foundation for welfare economics. It led to several attempts at an improved theory of income distribution.

Pareto always insisted that to understand his *Manuale*, one needed to know his *Cours*. In a typical misreading, J. R. Hicks complained that in the *Manuale*—by now a classic on the theory of consumption—the problems of capital and interest were hardly noted (Hicks 1950), ignoring their extensive treatment in the *Cours*.

It was Pareto's intention to show 'by examples rather than declarations to prove the relation between economic phenomena and other phenomena of society' (Pareto 1994, Foreword). Thus, it becomes clear how deplorable was the omission, in the French edition of the *Manuale* (Pareto 1981) of Pareto's Foreword or *Proemio*. Still, improvements had been made to other parts of the French edition, including Pareto's mathematics. He was of the opinion that 'pure' theory was applicable only to the flow of goods and trade within a 'purely' competitive economy. Yet, the reality of monopolies, cartels, and trusts asked for a different description of modern markets and their mechanisms. Eventually, he discarded his entire theory of economic equilibrium as a 'dead end,' in spite of his groundbreaking anticipation of what later essentially came to be called the theory of monopolistic competition (cf. the French edition of the *Manuale*, Vol. 3, 40–8, 160–64, Vol. 5, 8–9, 71; App. 141). With reference to the effects of economical cycles, Pareto already differentiated between their objective and subjective sides. In this, he could claim no less a predecessor than Montesquieu.

Pareto's final great work, the *Trattato*, was preceded by the brief *Mythe vertueuse et la littérature immorale* (Pareto 1911), an unforgiving settling of scores with any kind of literary censorship. Taken to its logical conclusion, Pareto argued, censorship would have to call for all of world-class literature to be censored—starting with the Bible.

In the two volumes of his *Trattato di sociologia generale* (1983), Pareto undertook the immense task of integrating his economic and social analyses. It had long been clear to Pareto that for any model of economic action fully to grasp reality it had to encompass a theory of society. Next to those actions described as logical, recognizably illogical actions had to be equally accounted for. Such actions called illogical by Pareto are regularly cloaked by pseudo-logical explanations. On this insight, Pareto erected an entire sociology of knowledge (cf. Eisermann 1987

p. 170ff.). Logical actions, to Pareto, were not synonymous with rational actions, however. For any act to be described as rational, it would have been necessary actually to look into the mind of the social actor. Pareto did not think such introspection was feasible. Rather, he conceptualized such actions as residual social facts. Thus, Pareto arrived at an inventory of six residues, in which instinct of combinations and persistence of aggregates were the most important ones.

He distinguished between two groups of economic actors: 'rentiers' and 'speculators.' Rentiers in general are secretive, cautious, timid souls, mistrustful of all adventure, not only of dangerous ventures but also of any venture to have even the remotest semblance of not being altogether safe (Pareto 1983, 2313). Pareto's rentiers are ruled by aggregates of persistence and his speculators by their instinct of combination. Speculators

are usually expansive personalities, ready to take up with anything new, eager for economic activity. They rejoice in dangerous economic ventures and are in the watch for them, but they work underground and know how to win and hold the substance of power, leaving the outward forms to others (Pareto 1983, 2313).

Accordingly, Pareto expanded his analysis of the economic equilibrium into an analysis of the social equilibrium (Pareto 1983, 2067–87). The crucial movement inside the system of society is construed as *circolazione delle classe scelte*, class circulation. Society is then ruled by fractions, or minorities, which are subject to a continuous turnover, or exchange (2025–46 and throughout).

Pareto always insisted that his 'pure' theory simply was an integral part of his overall economics, and that his economics necessarily formed part of his sociology. He claimed to have introduced the principle of relativity to the social sciences. He took equal pride in his anticipatory powers of foresight. Like his contemporary J. M. Keynes, he foresaw the catastrophic repercussions of the Treaty of Versailles—for purely economic reasons. As early as 1917, he asked, 'whether the Pax americana will turn out to be as productive as the onetime Pax romana?' (Pareto 1960, Vol. 3, p. 240).

G. Eisermann

Parietal Lobe

The parietal lobe is the part of the cerebral cortex lying between the occipital and frontal lobes, and above the temporal lobe (see Fig. 1). It is named for its proximity to the parietal bone, the wall of the skull (from the Latin *paries*, wall). It has five major functions: the primary analysis of somatic sensation (touch, the position of the limbs, temperature); the analysis of

Figure 1

The four major lobes of the human and Rhesus monkey brains. The lobes are labeled in the human brain. In both the monkey and the human brain, the surface area of the cerebral cortex is so great that the cortical surface must be folded so that some tissue is on the gyral surface, for example the postcentral gyrus, and other tissue is hidden deep inside clefts called sulci. The major sulci of the parietal lobe are labeled in the monkey brain, as well as the postcentral gyrus. The lobes in the monkey brain have the same shading as the lobes in the human brain

space using all sensory modalities; the specification of spatial targets for the motor system; the generation of attention; and the analysis of visual motion. Our first understanding of parietal function arose from the analysis of the deficits of patients with lesions of the parietal lobe (Critchley 1953). Subsequent insight into the mechanisms of parietal function came from neuro-anatomical and neurophysiological studies.

The importance of the parietal lobe was apparent to neurologists such as Hughlings Jackson, Dejerine, Head, and Holmes early in the twentieth century. They discovered that humans with parietal lesions had difficulty with tactile perception on the side of the body opposite the lesion (the contralateral side): they were not completely unable to feel stimuli, as they might be after a lesion of the spinal cord, but they had relative deficits: they might be able to feel touch, but not pain or temperature; they might perceive touch but have difficulty localizing the stimulus; they might have difficulty knowing the position of a limb in space; they might have difficulty identifying an object placed

Figure 2

Drawing of clock by a patient with a right parietal lesion. Note that the numbers are displaced to the right, as if the patient is neglecting the left side of the drawing, and that the relationships of the numbers to each other are also disturbed, for example the 10 is to the right of the 9 (reproduced with permission of M. Critchley from *The Parietal Lobes*, 1953)

in their hand without looking at it—for example, they would not be able to reach into a pocket and pull out a key, leaving coins behind. Stimuli were often perceived to be less strong on the affected side than on the normal side of the body, and comparative discriminations were coarser. Sometimes patients who can appreciate a stimulus on an affected limb when it is the only stimulus touching them cannot appreciate it when two stimuli are applied simultaneously, one on the affected limb and the other on the normal limb. The most dramatic parietal deficit is anosognosia—patients, especially those with right parietal deficits, are entirely unaware of the limbs on the contralateral side: they think that a leg in bed with them belongs to someone else.

Patients with parietal lesions do not have deficits limited to the tactile or somatosensory domain: they have striking visual deficits as well. Patients with right parietal damage tend to neglect the left visual field, the left side of space relative to the midline of their bodies, and the left side of objects (see Fig. 2). When they draw a clock they cram most of the numbers on to the right side of the clock, neglecting the left; when they attempt to bisect a line they place the midline near the right end of the line rather than the middle. After this florid neglect has recovered, right parietal patients often still neglect a stimulus in the affected visual field when another one is presented simultaneously in the normal visual field. This deficit is interpreted as a deficit in visual attention: patients with parietal lesions are less efficient at shifting their attention into the affected field than into the normal field.

Patients with parietal lesions often exhibit optic ataxia, the inability to coordinate their movements using visual cues. They have difficulty knowing where

Figure 3

Enhancement of the response of a neuron in the lateral intraparietal area to an attended stimulus. The upper display is a raster diagram: in this diagram each dot represents a single action potential. Each line is a single presentation of the stimulus, which is accomplished by having the monkey make a saccade that brings the stimulus to the proper part of the retina. The graph underneath the raster display is the average firing rate of the neuron as function of time. The vertical line represents when the stimulus arrives in the part of the retina to which the cell responds. The cell responds immediately after the saccade. When the stimulus has suddenly appeared 400ms before the eye movement, and has the attentional effect of an abruptly appearing object, the response of the cell to the appearance of the stimulus at the proper part of the retina (attended stimulus, left) is much greater than the response to the stimulus when it has been present in the environment for a long time, and is therefore not attention worthy (unattended stimulus, right) (adapted from Kusunoki et al. 2000)

objects are relative to their body. They misreach for objects, and make inaccurate eye movements toward them. They also have difficulty transmitting visual information to the motor system. When humans reach for an object, they open their hand to the approximate width of the object before their hand arrives at the object. Thus, people reaching for a can of soda will open their hands wide to accommodate the can; people reaching for a pencil will open theirs narrowly, just to accommodate the pencil. Patients with parietal lesions cannot do this, but reach for all objects with a stereotyped hand posture. The brain mechanisms that drive limb movement have no access to the detailed visual aspects of a target, even though they might know the spatial location of the target. A remarkable aspect of parietal deficits is that, although patients do not know where an object is, they have no difficulty telling what that object is—they know, for example, that the examiner is holding a wristwatch in front of

them, but cannot find it to reach for it. They exhibit constructional apraxia—when asked to duplicate a block design they are unable to place the blocks in proper relationship to each other, but instead leave them in an unordered jumble even though they choose the proper blocks. Patients with lesions of the parietal cortex on both sides of the brain have difficulty shifting their attention away from the current object. The result of this deficit is that they only describe one in the world at a time—they may see a dog's nose but not its ears, for example. They cannot use eye movements to explore the visual world. Patients with small lesions of the parietal cortex occasionally exhibit a specific deficit for the analysis of visual motion and the transmission of this information to the motor system. They have deficits both with the motor aspects of visual motion, for example, they cannot follow a moving object with their eyes; and they have difficulty with the perception of motion—knowing the speed of an object, or judging the predominant motion of a moving random dot pattern.

Space is not represented in a unitary fashion in the parietal cortex. Instead it seems to be organized in concentric spheres, or workspaces, that correspond to the range of action of certain motor systems. Patients with small lesions of the parietal cortex may have these different workspaces affected differentially. Thus a patient who can localize a nearby stimulus by reaching out and touching it with an arm may not be able to localize a stimulus further away in the same direction by touching it with the beam of a laser pointer. These are not merely deficits in movement—the patients show perceptual distortion, such as an inability to bisect a line, in the affected workspace.

Recent studies in neuroanatomy and neurophysiology, especially those done with the Rhesus monkey, have been able to illuminate the brain mechanisms whose destruction causes the dramatic clinical symptoms of the parietal lobe. The brain is a network of information-processing cells called neurons. Each neuron serves as a node in this network, receiving information from other neurons, often in different areas of the brain, and transmitting this information to other neurons. By studying the cytology of the parietal lobe and its connections with other parts of the brain, neuroanatomists have been able to divide it into a number of functional subdivisions. Neurons transmit information by emitting a series of electrical impulses called action potentials. If a neuron responds to a stimulus it issues a burst of impulses in response to the appearance of the stimulus. By monitoring the electrical activity of neurons in the parietal lobe of monkeys that are awake and performing behavioral tasks, neurophysiologists have begun to understand the signal processing that enables the parietal lobe to perform its function in the generation of human behavior.

Physiological and anatomical studies have subdivided the parietal lobe into a number of distinct

areas which perform the various different functions whose deficits appear in patients with parietal lesions. The most anterior part of the parietal lobe is the primary cortical area for somatic sensation. Most of the posterior parietal cortex, starting with the posterolateral bank of the intraparietal sulcus is concerned with space and attention. The most posterior parietal area, in the superior temporal sulcus, is important in the analysis of visual motion.

The primary somatosensory cortex consists of four subdivisions, cytoarchitectonic areas 3a and 3b, located in the posterior bank of the central sulcus, and areas 1 and 2 located on the surface of the postcentral gyrus, the brain surface between the central and intraparietal sulci. Each of these subdivisions receives projections from the somatosensory parts of the thalamus, the way station between the spinal cord and brainstem, and the cortex. Areas 3a and 2 are responsible for deep bone and muscle sensation, including the muscle spindles that measure muscle length, and joint sensors that describe limb position. Areas 3b and 1 are responsible for sensation from the skin. These areas project backward to area 5, on the postcentral gyrus and the anterior bank of the intraparietal sulcus. This area integrates the various primary sensory signals, and transmits somatosensory signals to the premotor cortex so the information can be used for not only the perception of somatic sensation but also the coordination of movement. Single neurons in the anterior parietal cortex describe the properties of tactile stimuli in a very precise manner: for example, Mountcastle showed that neurons responsive to vibration describe the intensity and frequency of that vibration so accurately that a computer could construct the nature of the stimulus by decoding the neural pulse train.

The posterior parietal cortex is subdivided into a number of areas. Those located in the intraparietal sulcus associate somatic sensation, vision, and audition for the analysis of space, and the description of this world for action. Many of the areas in the intraparietal sulcus describe particular workspaces (Colby and Goldberg 1999). The physiological properties of these areas have been studied extensively in the Rhesus monkey.

Perhaps the best-studied area of the monkey parietal cortex is the lateral intraparietal area (LIP). This area describes distant space, the space that primates explore with their eyes. It projects to the frontal eye fields and the intermediate layers of the superior colliculus, brain areas known to be important in the generation of the rapid eye movements (saccades) that human and non-human primates use to explore their environment. It also projects to areas in the temporal lobe, TE and TEO in the Von Bonin and Bailey nomenclature, which are important in the analysis of pattern. An important connection between the generation of saccadic eye movements and the analysis of the visual world is the process of attention, the selection of

objects in the world for special analysis. In general, human and nonhuman primates pay attention to the targets for their eye movements, and saccades and attention are closely linked, but they can be dissociated in certain cases—for example juvenile Rhesus monkeys certainly pay attention to the alpha male of their troop, but they never look directly at him. Animals attend to stimuli either because the stimulus is relevant to the current task, or because the stimulus is naturally attention worthy, stimuli that are, in the words of William James, ‘big things, bright things, moving things, or ... blood’ (James 1890). For example, stimuli that appear abruptly in the visual field inevitably draw visual attention.

Neurons in LIP respond both to saccade targets and to attended stimuli that are not necessarily the targets for saccades. These neurons respond to visual stimuli, and their activity is modulated by whether the animal is paying attention to the stimulus. Neurons in LIP respond more to attended than to nonattended stimuli, independently of whether those stimuli are attended to because of their importance to the task or because they are in the class of stimuli that inevitably draw attention. Presumably it is the absence of this attentional modulation system that impairs the ability of parietal patients to attend to stimuli in the world contralateral to the lesion. Neurons in LIP also respond to sounds when the monkey attends to them (Andersen et al. 1997). A classic task in which to study the activity of neurons is the delayed saccade task.

In this task a monkey looks at a spot of light and another one flashes briefly in the visual field. A few seconds later the original fixation point disappears, and the monkey makes a saccade to the spatial location of the now vanished saccade target. Neurons in LIP respond to the stimulus, and then continue responding even though the stimulus has disappeared. This activity has been interpreted as either maintaining the memory of the saccade target, or focusing attention at the saccade target. It is probable that this area of the brain supports both functions: focusing attention on spatial locations, and providing the oculomotor system with information about the location of potential saccade targets. LIP serves as a model for the other, less well studied areas of the parietal lobe: neurons specify possible targets for the action appropriate for the workspace, as well as responding to attended objects in that workspace.

The most posterior part of the parietal cortex of the monkey lies in the superior temporal sulcus. This area is important for the analysis of visual motion. Neurons in the middle temporal area and the middle superior temporal area are specialized for the analysis of visual motion, and respond selectively to stimuli moving with certain speeds and direction. Electrical stimulation of these areas can affect monkeys’ perception of motion, and lesions in these areas render monkeys unable to follow moving stimuli with their eyes, or to make judgments about the quality of visual motion.

Parliamentary Government

1. Development of Parliamentary Regimes and Democracy

Parliamentary democracy is the product of the twentieth century and in many countries developed only after 1918. There were some attempts to create such a system during the European revolutions of 1848 without leading to consolidated systems. What Huntington has called the first long wave of democratization (1828–1926) in the light of research on parliamentary systems was only parliamentarization. Parliamentary government is characterized by a government *responsible to the majority in parliament*. Democracy was added to the parliamentary regimes only later. The minimal criterion of democracy is *universal suffrage*. In most countries with a regime of constitutional monarchy, such as Britain, Scandinavia, or the Benelux countries, democracy was introduced later than parliamentary regime. Only in some rather authoritarian monarchies was democratic universal suffrage introduced or preserved without granting a parliamentary regime with responsible government (France 1851 in the Second Empire, Germany 1871 in the Empire of Bismarck) (see Table 1).

Only in a few countries (France, Finland, Sweden) was the process of parliamentarization and democratization synchronized. A continuously democratic parliamentary regime existed only in France. Even Britain—the mother of ‘parliamentary government’—in the nineteenth century could not be called a

Table 1

'parliamentary democracy' (cf. Table 1). There was a divergence of *parliamentarization* (mostly implemented by liberal majorities which were reluctant to add universal suffrage to the system) and *democratization* (frequently introduced under the pressure of radicals and socialists). These groups were initially unwilling to accept the checks and balance of the liberal parliamentary regime and advocated a democratic regime with many features of plebiscitarian instead of representative democracy. Only when they came to power did they slowly accept the rules of the game which were mostly developed in former constitutional monarchies.

Democratization in some countries has ruined the parliamentary system (Italy, Austria, Germany, Spain) when counter-regime forces gained power. In other established parliamentary systems the regime in the 1930s came to the brink of a collapse (Belgium, France) under the pressure of right-wing extremism. Only after 1945 and the disastrous experiences with authoritarian or even totalitarian dictatorship, were parliamentary government and democracy combined in peaceful co-existence. Some countries (such as the Federal Republic of Germany) even then, however, showed a tendency to emphasize the legal state and *representative parliamentary government* much stronger than *democratic participation*. The theory of constitutional and representative government did not easily accept parliamentary democracy but interpreted the preponderance of the parliamentary majority in terms of a rather mechanistic system of checks and balances and 'mixed government.' Because responsible cabinet government developed first in Britain and Belgium, the jurists for quite a time used the term '*Coburg government style*.' Only since the 1830s was the term 'parliamentary government' accepted in Britain and France and the regime was recognized not only as a mode of governance but as a *regime sui generis* which made the old typologies of regime types according to the number of rulers rather obsolete.

2. Types and Criteria of Parliamentary Democracy

There are many types of parliamentary government, but most of them have developed common *institutional* criteria.

(a) *Compatibility of parliamentary mandate and ministerial office* (exceptions are the French Fifth Republic, Luxembourg and The Netherlands) in order to guarantee close cooperation between the parliamentary majority and the executive.

(b) Prime ministers are normally *members of parliament*.

(c) The government has to have the confidence of the parliamentary majority. *Ministerial responsibility* is not defined in terms of legal responsibility as in

dualistic constitutional monarchies. The government has to resign in the event of a vote of no-confidence unless it chooses to ask the head of the state to dissolve parliament in order to give the electorate the opportunity to resolve the conflict.

(d) Parliament controls the *government by raising* questions, exercises the right to interpellate and set up committees of enquiry, which facilitates the decision about whether the strongest sanction or a vote of no-confidence should be used. This right is shared by dualistic presidential systems, apart from the possibility of toppling the head of government and his or her cabinet.

(e) Some analysts have postulated as an essential feature a formal vote of the government at its first meeting with parliament (*investiture*), as in the French system under the Third and Fourth Republic and in Italy, or even demanded the *formal election of the prime minister*, which was developed in the German Basic Law of 1949. Most parliamentary regimes do not accept this condition.

(f) More widespread is acceptance that *parliament* should be *dissolved* if the prime minister has lost the confidence of the parliamentary majority. Sometimes this has not been instituted, for example in Norway and Israel. In other cases the legal possibility of dissolution has become inapplicable because it has been abused by unparliamentary presidents, as in the Third French Republic (when President MacMahon dissolved the Chamber of Deputies in 1877).

Besides the minimal institutional criteria, certain social structural features are essential for the consolidation of parliamentary government:

(a) *Organized parties* to facilitate the building of parliamentary majorities.

(b) Party-building to facilitate the development of *cabinet solidarity*.

(c) Development of the *office of prime minister*. In early systems where the estates dominated, and even in certain absolutist monarchies, the power centers—the estates or the crown—impeded the activities of first minister. A certain *hierarchization of the ministerial council* also strengthens cabinet solidarity.

(d) Development of a *political culture* favorable to appropriate parliamentary behavior and alternating government.

Not all these institutional criteria can be found in every type of parliamentary system. Therefore subtypes have been proposed. Most ideological is the distinction between *authentic British parliamentarism* and the allegedly *inauthentic parliamentary system of the French type*—close to revolutionary government. Latecomers to parliamentarization, such as Germany (1918) and Sweden (1917), have often denounced the dangers of the French type, especially the German school of Redslob.

Oddly enough, France itself has reacted strongly against the shortcomings of the parliamentary system of the Third and Fourth Republics. De Gaulle's

constitutional ideas, close to those of Carré de Malberg and later developed by Michel Debré were first pronounced in 1946 in the famous speech of Bayeux but failed to obtain majority when the Fourth French Republic was developed in 1946/47. But De Gaulle got his revenge when the Fourth Republic collapsed and he was able to shape the institutions of the Fifth Republic according to his ideas. A new system was born that since Duverger has been called the *semipresidential system*.

In spite of its name this was clearly a subtype of parliamentary government though the double responsibility before parliament and the head of the state—which existed in constitutional monarchies such as that of Louis Philippe—re-emerged. But in the long run the dominance of parliament in executive-legislative relations is re-established. De Gaulle's new system was not new at all: it had developed as a Republican type of constitutional regime from 1848 (the Second French Republic, 1848–51) and re-emerged in the Weimar Republic (1919) and Finland. Semipresidential systems are not a mixed type, not even the 'three-quarter presidential system' that Yeltsin tried to develop. The backlash of a humiliated legislature was felt in Russia in 1998 when Yeltsin was forced to renounce Chernomyrdin as prime minister and accept the parliamentary candidate Primakov.

3. Functions and Performance in Parliamentary Democracy

Parliaments were more powerful in times of parliamentary sovereignty without universal manhood suffrage than in modern parliamentary democracies. The main actor in parliamentary democracy is no longer parliament or government, but the two powers are linked together. This linkage has strengthened the prime minister in most parliamentary regimes, unless high party fragmentation and consociational practices of conflict resolution have weakened the head of the government. Parliamentary democracy seems to be misnamed because of much discussion on the 'decline of parliament.' Therefore, *cabinet government*, *prime ministerial government*, or *chancellor's democracy* became more popular to characterize the bigger parliamentary regimes.

Parliamentary systems have to perform various functions. There is no general decline of parliament but rather a change of the main functions of the system. *Parliamentary control* is weakened in systems with close relations of parliament and government, interlaced by party government. The *controlling functions* declined or shifted to other institutions from constitutional courts and courts of account to the mass media. *Representation and articulation of interests* in the systems has changed over time. The *legislative function* is still important because more

social problems are regulated in modern democracies than in old constitutional regimes. The *recruiting function* of the system, however, is strengthened after democratization of the parliamentary regimes.

Parliamentarians have become less removed from their voters in terms of *social structure*. What has been called *virtual representation* in early parliaments for those not eligible to vote in *postparliamentarism* is true of the social ties between deputies and voters. But people have adapted to this development and demand less strongly to be represented by members of the same region, the same sex, the same profession, or the same social class. The influence of voters on the selection of representatives is still mediated by the parties and their formal members. Primary elections can undermine the selecting function of the parties among other disadvantages, such as a lower voter turnout in the general election. Modern democracies are not ruled according to President Lincoln's Gettysburg formula of government *of* the people, *by* the people, and *for* the people. The distance of the representatives is compensated for by increasing *responsiveness* and sensibility to the wishes of the voters. Government *for* the people in the modern democracy of fluctuation of mass public moods has increased rather than decreased.

Nonetheless the deparliamentarization of democracy is lamented. This has a *domestic political* side. At the stage of policy formulation, the practice of expert committees working together with the government is growing stronger. In the decision-making arena, the government is the most important initiator of legislation. Informal initiatives behind the formal initiatives of advisory boards, constitutional courts, or international organizations are further undermining the part played by parliamentarians in legislation. The penetration of interest groups into the work of ministers and parliament has shifted the preparatory work to a round tables of extraparlimentary committees and working teams. But parliament is not just a rubber stamp to ratify the decisions of networks outside parliament. Parliaments, formally the institutional seat of the people's sovereignty, represent the framework for the coordination of networks of actors from parliamentarians, party strategists, interest groups, ministry officials and in federate states the federate units. The cosy triangles of early American parliamentary studies, composed of parliamentarians, bureaucrats, and interest groups, have become unc cosy squares, since party steering was rediscovered in the 'legislative Leviathan.' In federal states such as Germany, deparliamentarization at the Länder level has led to greater participation of the Länder in the national decision-making process via intergovernmental decision-making. This further actor has been added, making an unc cosy pentagon. The Maastricht Treaty has increased the number of areas that are subject to EU rules and legislation. With growing competence at the EU level, lobbying at that level is

likewise growing. Meanwhile, national parliaments—more than the executive—have been downgraded to the position of lobbyists. Paradoxically the *democratization* of the European Union has led to *deparliamentarization* at the national level. Until 1979, Members of the European Parliament were tied to the national parliaments, but since the introduction of direct elections this has no longer been the case. However, the European Parliament does not yet pose a real threat to the national parliaments as it can only draw up laws when asked to do so by the Commission. Formally, EU legal acts are passed by the Council of Ministers and not by the European Parliament.

There are three threats to parliamentary democracy:

(a) In the Process of *regionalization*, regional assemblies will try to strengthen themselves via regional politics at the cost of national parliaments.

(b) In the process of *Europeanization*, more and more domains of the national parliaments will be regulated by the EU. This process will be supported by the activities of the European Court and the gradual standardization of the national legal systems.

(c) In the process of *globalization*, a consolation at the national level is the fact that worldwide organizations such as the World Trade Organisation and GATT are starting to retaliate to the EU for what it did to the national decision-makers because the room for maneuver of the European organizations is increasingly limited by the global level, although still strongly limited in some arenas.

Parliaments, History of

Nowadays, a Parliament is a central institution of the democratic state under the rule of law. The term parliament comes from French and describes a forum in which social understandings are reached by verbal negotiation, through the act of speaking. A Parliament is a representative institution, elected by direct universal suffrage. It plays an indispensable role in the workings of the State, as an active participant in the coalescing of political will, in public management, and essentially through conduct of the legislative process and concentration of the ruling elite. The decisive function of policy legitimization performed by parliaments is central to representative democracy which is the predominant system of political organization in contemporary states. Experience of direct democracy, which dispenses with the representative parliamentary system or acts in parallel to it, is generally limited to referendums, Switzerland being among the few countries that practice direct democracy on a regular basis. A Parliament is an assembly of public delegates who receive a mandate for a limited period, are voted to office through elections based upon a pluralistic political-party system, and serve as a channel for the expression of the opinions of society.

The approaches of political scientists and historians to the study of parliaments are closely related. Most contemporary researchers apply the insights of both disciplines in their efforts to analyze and explain the institutional structures and workings of parliaments. Comparative studies of the trajectory of societies, of the formation of states, and of the composition of their social and economic groups are the components of research on representation, participation, and decision-making processes conducted through and by means of parliaments. The achievement that parliamentary institutions represent, in terms of the development of democracy within society throughout the nineteenth and twentieth centuries, provides the social sciences with ample scope for research. Political science, sociology, and history continually delve into the origins, composition, work methods, social relevance, political prominence, and social roles of parliaments.

1. Functions and Types

The functions of parliaments have differed according to the system of government. Various terms may

designate a parliamentary institution according to the different systems, such as: parliament, court, assembly, council. Under a parliamentary system, executive power emanates from the legislative branch invested in parliament, and governments hold office and remain in power so long as they enjoy the confidence of the parliament. Under a presidential system, parliament serves as a counterpoint to the political legitimacy bestowed upon the president through direct presidential elections. Parliaments also exist in nondemocratic regimes, such as the fascist dictatorships and 'democratic peoples' republics' of the twentieth century. Under such systems they tend to be mere puppets or facades since they exercise no real power but rather serve as rubber stamps to endorse the power of the government, devoid of the legitimacy bestowed by a pluralistic party system and in the absence of representative electoral processes.

Depending on the process leading to their formation, parliaments can be classified according to three criteria: composition, action, and structure. Composition is subject to two variants: the first of these relates to criteria based on noble birth or propertied status, whereas the second is based on universal suffrage. Functionally speaking, contemporary parliaments can also be classified as bicameral or unicameral, depending on the constitutional framework of the State, which may have opted for a single chamber or for two chambers. In any case, the chamber (or at least one of the chambers) ought to be elected directly by the people in free elections.

In functional terms, parliaments may be classified as 'active' or 'deliberative.' Active parliaments are those that, within a parliamentary system, have the power to appoint and support the government, as is the case in most modern parliamentary democracies. The so-called deliberative parliaments are those that have no direct responsibility for the business of government, and include the pro-forma parliaments tolerated by authoritarian regimes. Under a presidential system, as a counterpoint to the legitimacy of the 'working' executive branch, the parliament assumes a predominantly deliberative role. These characteristics apply equally to unicameral and bicameral parliaments, in both federative and centralized states.

It is the decisive role performed by parliaments in the process of forming governments and providing them with support that has given currency to the term Parliamentary System to describe the form of government in which empowerment and support of the Executive Branch are dependent on a vote of confidence from the parliament. This definition applies to the form of government a term that expresses the legitimacy that stems from the legislative branch in its executive form. Under a presidential system in which the Executive is the predominant Branch of Government, as is the case in the United States, the Head of State is voted to office by direct elections and consequently his legitimacy competes with that of the

parliament. In both parliamentary and presidential systems, the parliament is said to embody the Legislative Branch and its political legitimacy stems from the ballot.

2. Origins

Modern parliaments stem from two roots. The first of these is the corporative assemblies of the Estates that were summoned under the *Ancien Regime* in Europe, and the second, the broad-based popular representation originating from revolutionary movements. The first model of corporative representation brought together the three Estates—namely, the nobility, the clergy, and the ‘third estate’ which evolved gradually into a form of parliamentary representation as sovereign rulers required assent to levy taxes and make war. This first version of the dependence of the sovereign ruler on an institution of a parliamentary nature did not lead directly to democracy nor to recognition of popular sovereignty. The origin of these lies in the second root of modern parliaments—the popular revolutionary root—from which stem: the origins of the process of definition of popular sovereignty, the concept of citizenship, the legitimacy of power based on representation and the delegation of sovereign power, the rule of impersonality of the law within a context of absolute civil equality among citizens, the extension of such rights to all adult citizens within society and the adoption and consolidation of liberal democracy, the expansion of suffrage and political parties, the constitution of government and of its control (under both the parliamentary and presidential systems), and the expression of popular will through the ballot. Both roots reflect anti-absolutist sentiments and it is from them that a representative democratic model, with elections at predetermined intervals, developed.

Both these origins of parliamentary power are clearly preserved and apparent in the structure and functioning of the British parliament. The House of Commons, based upon the weight it amassed in the civil war of 1642–9 and the upon manifestation of its social powers in the Glorious Revolution of 1688–9, assumed its role of expressing the collective will as a source of power detrimental to that of the Crown. The result of the revolution, which established the right of parliament to chose a new sovereign, is reflected in the jusnaturalist and contractual arguments presented in Locke’s *Two Treatises on Civil Government* (1690)—one of the principal theoretical works in support of the legitimacy and controlling powers of parliament.

The House of Lords, with its elitist composition, preserves the corporativist tradition of the Estates. Modern French tradition, established with the Jeu de Paume Oath of June 20, 1789 at the advent of the French Revolution, signals a break with the system of Estates General of the *Ancien Regime* and use of the

term Parliament to designate the judicial and notarial functions, as it had since the twelfth century. The parliamentary assembly installed in the very earliest days of the revolution enshrined the principal of popular sovereignty. In both the British and the French cases, affirmation of the principle of popular sovereignty arose from revolutionary movements, whereby the political absolutism of European states was substituted by constitutionalism. The role performed by a representative system in the formation of the United States is unique. The affirmation of the will of the Americans against unconditional rule by the British Crown led to the establishment of a community-based version of the decision-making process, similar to the community practices of the Protestant congregations, which served as a collegiate political model for the provincial and continental congresses, in which no form of corporative representation was present.

3. Evolution

At the onset of the nineteenth century there were three types of parliaments: mixed-popular and aristocratic-bicameral under the English model; the French unicameral, popular model; and the American bicameral, popular and federalist model. In Western Europe and in the Latin-American republics, an era of constitutionalization began. Both monarchies and republics adopted political systems dependent on representative legitimacy. Under parliamentary systems (in which the Government is dependent on investiture by the Legislative Branch), and under presidential systems (in which the Executive is chosen by direct elections), parliaments assumed increasing importance in political life. Parliament became the forum for representation and expression of social and economic forces, where the repercussions of rights claimed took on resonance and the extension of political and civil rights was played out.

The role of parliaments evolved during the course of the nineteenth century from being initially consultative to being deliberative. The legitimacy of parliaments became independent of the legitimacy of the sovereign upon emerging from the electoral process. As a consequence of electoral and census systems which, throughout the 1800s, maintained cultural and economic distinctions among citizens, despite their all being held (theoretically) equal before the law, parliaments maintained an indirect corporative dimension until the institution of universal suffrage. Such distinctions were based on the systematic exclusion of women and the preference for the rich, the well-born, and the literate.

The itinerary of consolidation of the power of the Legislative Branch was implemented in different ways under the North American presidential, the British

parliamentary, and the French and German parliamentary models. The United States Congress reflects the federative structure of the State and the fact that the United States spent the nineteenth century engaged in a process of expanding its frontiers and acquiring new territory. Furthermore, the political model adopted by the American Congress implies that each state of the federation, through actions taken by its own political spheres, has joined the Union. The principle of legally joining a federation of states, together with that of popular sovereignty, is enshrined in the bicameral parliamentary systems predominant in federative states (such as the United States, Canada, Australia, Brazil, India, Austria, Mexico, Argentina, Germany, Japan, and Indonesia). In centralized states, bicameralism is the result of the continuity of mixed forms of representation, with roots stemming back to the Estates and to popular sovereignty. Both the British and the French parliamentary systems provide examples of such evolution. In both cases, tradition has been partially preserved through the upper house (the House of Lords and the Senate), whereas popular representation is ensured by the Lower House (the House of Commons and the National Assembly). This model was also adopted by the Scandinavian monarchies and also, at specific times, by such states as the German Empire (1871–1918) and the multinational Austrian–Hungarian Empire (1848–1918).

Parliaments emerged upon the European scene as a counterpoint to monarchic autocracy. In their contemporary form as ‘parliaments of citizens,’ they emerged from an extensive line of development going back to the principle of egalitarian representation first put forward in the eighteenth century. The parliamentary model of the late twentieth century is the fruit of the maturing of philosophical concepts with respect to human rights and the separation of powers. As the twenty-first century dawns, there is widespread social awareness that there can be no exercise of power without political representation, and that this resides in the legislative bodies. The transformation of political regimes into fully-fledged democracies has led to an expansion and diversification of the roles of parliaments. To the role of authorizing tax collection has been added deliberation of public budgets, supervision of government actions, and full participation in decisions regarding public policies.

The reform of electoral systems and extension of suffrage have placed on the stage of public and social life the professional politician, a party member who represents specific interests. The principal interest that became enshrined over the length of the nineteenth century—from the French Revolution to the end of World War I—was to force the acceptance of, respect for, and practice of popular sovereignty as the source of the legitimacy of all power.

Central to an understanding of the evolution of parliaments is the concept of popular sovereignty. It was the new element that entered the political scene in

the eighteenth century, whereby Monarchic authority—though still enjoying wide support—was no longer accepted as being absolute, nor independent of social support. It found expression in parliamentary democracy which essentially signifies a system in which government is made up of a nationally-elected assembly to which it is accountable. Acceptance of this concept was consolidated during the course of the nineteenth century when the ideal of democracy became associated with the parliamentary system of government.

‘Active’ parliaments—the importance of which has increased remarkably since 1945 and is still increasing at the onset of the twenty-first century—have taken on a direct responsibility for furthering the public interest. This is in line with a historic trend, initiated in the 1790s, of delegating sovereignty to elected representative bodies. In such parliaments, the house assumes not only the role of deliberating themes of interest to society but also of making decisions relating to public policies stemming from them. Under presidential systems, as is the case of the United States, the powers of the Executive are legitimized directly by popular vote, independently of parliament. Although this is true in terms of the origin of legitimacy (the ballot), it does not mean that the concrete exercise of power is free of controls. On the other hand, the extension of suffrage and the continuous rate of development of political participation since the 1830s have brought about changes in the exercise of power which have not excluded the presidential systems. Though it may even be possible to govern without parliament—against parliament it is not possible to govern. Though a strong presidential government might tend to ignore collective assemblies, nonetheless, the democratic framework of the State serves to counterbalance the relationship. Parliamentary democracy is an achievement of the Western European States and, increasingly of a number of Latin American and former communist Eastern European States. It is also the result achieved by certain nations of the British Commonwealth which, since becoming independent of Britain, have incorporated the parliamentary system of government. Such is the case in Canada, Australia, India, and New Zealand. Democratic and parliamentary systems are rarer and less stable in Africa, the Middle East, and the Far East.

The expansion of suffrage, resulting in mass democracy and recourse to regular popular participation (formalized through political parties or indirectly through lobbies or special interest groups), have caused parliaments to assume the roles of formulation and assessment of public policies (and of decision-making under parliamentary systems of government), particularly in the financial area (through the preparation of the budget and the exercise of control over its execution). The rate at which parliamentary institutions have assumed a leading role in the political process varies from one region to another. In periods

of economic expansion or of war, the active role of parliaments may go into retreat, as occurred in the *Belle Epoque* and during World Wars I and II. Under authoritarian regimes, of the left or of the right, it is not uncommon for parliaments to be merely irrelevant decorative trimmings to the institutional architecture (as was the case in Fascist Italy, Nazi Germany, in the communist countries, and under the military dictatorships of Latin America in the twentieth century). Beginning in the 1990s, successful experiences of systems of government centered upon parliaments have been adopted in various regions of the world. In Eastern European countries, the West European parliamentary model of political organization has been widely adopted, though it runs up against the tendency to fall back on a powerful Head of State with a presidential profile that is a legacy of the centralizing tendency of a communist past which lasted from 1945 to 1990. In Latin America, with the restoration of democracy that began in the 1980s, parliaments have taken on importance in a context clearly dominated by the presidential models of the North American type. In Asia, Japan, and India active parliaments have been the rule since the late 1940s. In Africa, although practically all countries have parliamentary institutions, the parliamentary model, whether active or deliberative, remains incipient and the role of parliaments largely irrelevant.

4. Future Prospects

Issues discussed when examining the history of parliaments fall largely into three groups: the external environment; domestic characteristics; and the political characteristics of parliaments. The external environment includes efforts to articulate four trends: the constitutional structure of parliaments, the administrative structure, the (political or electoral) system upon which they are based, and the interest groups with which they must interact. Their domestic characteristics comprise five factors that are decisive for the process of constituting parliaments: their members (their social and professional background, political experience and aspirations, and their degree of commitment to the legislative branch); parliamentary parties, committees, and houses as operational institutions, relations between members of parliament and their constituents as a reflection of social, economic, and cultural structures. The characteristics of their politics open up the possibility of studying parliaments as forums where the repercussions of short-, medium-, and long-term structures are felt and the way in which they reflect the dynamics of political decisions.

There are four principal trends in the historical research on modern parliaments: recovery and systemization of sources; sociological analysis of the

composition of parliamentary representation; a physiological examination of parliamentary speeches; analysis of the role of parliaments in public administration (the formation and control of governments, monitoring and assessment of public policies, and taking of measurements among the voters and public institutions). A great portion of these trends is typically European. In Great Britain and in Germany, for example, recovery of sources is an important approach when placing parliaments within a historical context. The same is true in Brazil, Canada, and Australia. In all these cases, this monumental work has been linked directly to the consolidation of their respective identities over time and to the legitimization of the democratic structures of the State. However, as also occurs in other walks of life, historical research trends evolve.

Not so long ago it was possible to write on the history of parliaments by concentrating solely upon formal texts. Causes and developments would be carefully taken into account, accounts taken down in writing in accordance with the level of detail required, and the consequences for political parties and other significant players in the political processes analyzed. In many of the older texts, an implicit (and sometimes explicit) premise recurring throughout the explanation of the causes and consequences of parliamentary life was that it was possible to chart their progress. History reveals the emergence of parliamentary democracy, as legislation expands the electorate (in accordance with the results of the census, especially in the nineteenth century), to a certain degree making the vote more equal and elections more 'honest.' It was perfectly possible to explore democracy through reference to certain key political dates in each country. Thus the British system came to be regarded as a paradigm by others, as it ensures mechanisms which guarantee the peaceful transfer of power.

Such emphases have been radically altered. First, historical research, in a more skeptical and less self-confident age, no longer seeks to chart the progress from a smaller to a larger state, not least because society at the end of the twentieth century has become much more ambivalent about the building of progress. Second, because much more emphasis had been devoted to continuity than to change (especially with respect to representative democracy). Third, research efforts (polling) at the constituency level have greatly increased. It is hardly surprising that such work produces revelations that do not support the progressive view. It could be argued that the nature of the political process has undergone changes for the worse, from the viewpoint of the lower classes. The way in which governments manipulate electoral laws and the rules defining constituencies and how majorities are defined (for example, proportional systems, simple majorities or mixed systems) have become relevant research themes in the field of historical research, the results of which are only now coming to light.

Furthermore, historians have begun to question the importance of the vote for participation in the political process. Indeed, a well-substantiated demand addressed to the administration is likely to be more effective than heated political speeches supported by a few votes in a legislative body. The parallel with nineteenth-century Brazilian politics (and the process of overthrowing dictatorships in the twentieth century, particularly in Latin America) are cases in point. As O'Gorman and Vernon showed for Great Britain, lack of voter participation has not been an obstacle to political participation. Members of Parliament must take a broad spectrum of interests into account if they wish to remain on good terms with their constituents. The right to vote does not necessarily bring with it access to political power. The suffragettes of the early twentieth century produced brilliant political propaganda, showing that educated, intelligent women with an interest in public affairs were denied access to the vote, whereas ignorant, vulgar, and drunken men were free to participate in it. In reality, such campaigns had a reach far beyond the mere exercise of the ballot: they were an affirmation of the importance of women in a stable political system.

Interest in electoral policies has been reinforced by detailed studies of elections, supported by long-term statistics. Such statistics have used materials that historians immediately recognize as being prime raw material for such studies. Voter registration records prior to the introduction of the secret ballot in Great Britain in 1872, for example, show who voted for whom. Such surveys make it possible to monitor changes in voting habits and to identify which candidates or parties lost favor with different social groups. The 'social geography' of elections and the 'sociological premises' of a given society thus become important instruments for historical analysis. Historical research brings together both the quantitative and qualitative techniques of the social sciences to obtain relevant results for the analysis of parliaments.

Political studies relating directly to social and occupational structures also touch upon two other lines of work carried out over the past 40 years. 'History from the bottom up' was in vogue in the 1960s and 1970s, when many researchers began to devote themselves increasingly to social structures. Attempts to discover the origins of the 'working class' and, somewhat later, of the 'middle class' involved deep social analyses. Historians more sensitive to issues of social class admit that political awareness plays a part in the issue. Indeed, class consciousness is related directly to the exercise and pursuit of power and in turn requires the existence of political structures that need to be changed. Nonetheless, in Europe, as of the early nineteenth century, debate on parliamentary reform became enmeshed in discussions on social class and on changes in the 'political culture.'

Another important intellectual development has been emergence of the so-called 'linguistic turn' which

began to influence historians in the 1980s. Detailed studies of language as a vehicle for conveying ideas, conducted by historians, have been inspired by radically new ideas borrowed from literary criticism. The relevance, and even the validity, of such an approach has engendered much debate among historians versed in the empirical tradition. Many are reluctant to accept that language can build its own realities, rather than having been invented to serve economic, social, or cultural needs. Unquestionably, extreme versions of poststructuralism, which claim that a text has no validity except in its own context, undermine any type of historical investigation in that they do not accept the notion of relative importance and suggest that change cannot be explained by intentional 'privilege' attributed to particular parts of historical documents. The 'linguistic turn' causes historians to be even more strict in the control of their premises on parliamentary discourse as a historical source. Language may effectively be used to mold ideas. Studies on demagoguery, populism, and '*caudilismo*,' and their influence upon the formation of parliaments in such countries as Brazil, Mexico, and Argentina, are pioneers in this field. The study of the language used by the Chartist reformers of parliamentary democracy in Great Britain, for example, shows that their real goal was political change.

A third theme relating to the expansion of the democratic process is treated under the term 'progress.' Research shows clearly that, when it comes to political change, progress is neither simple nor linear. Parliamentary history is related to, but not defined by, the history of democratization. 'Democratization' of itself is a highly problematic and contested concept. Nonvoters are not necessarily excluded from politics. No parliamentary reform ever 'grants power' to another social group—at any rate, not directly. Women do not all of a sudden hold power simply as a consequence of a scrap of paper called a 'law.' Current research trends show that the law is more likely to ratify a political order already in place than to introduce sweeping change. The recent development of supranational parliaments (the European Union, Mercosur) provides an entirely new field, into which investigative research is about to begin.

Historians have become more involved with continuities. Much of the historical research carried out in the 1980s and 1990s was accompanied by warnings about the dangers of economic reductionism, or of any other type of reductionism. However, the determination of historians to attempt to see things 'within their context' has contributed to the clarification of a series of relevant conclusions on the subject of parliamentary reform. They are now more aware that neither the 'top-down' explanations based upon the higher policies of central parliaments, nor the 'bottom-up' approaches that concentrate on extraparlimentary forms of pressure, are of themselves sufficient. The emphasis has swung to the need to understand the

intricate interrelations of the complex factors which created the political culture of the twentieth century and, above all, World War II. The changing methods and interpretations nonetheless confirm the central role of parliaments in this culture.

Parsons, Talcott (1902–79)

From the late 1940s to the mid-1960s, Talcott Parsons was the single most influential social theorist in the world. A developer of what is now popularly called 'action theory,' 'functionalism,' and 'structural-functionalism,' Parsons spent his entire career at Harvard University, which helped considerably in institutionalizing his ideas and also in providing him access to talented graduate students. By the 1950s, his publications became a major part of what was literally a 'common curriculum' for graduate students in all major sociology departments—as well as in many of the best political science departments. By being institutionalized in this way, Parsons' publications elevated the rigor of American graduate training in sociology in particular. More than anyone else, he also defined the 'classic' theoretical tradition for sociology as a discipline and then added a more abstract, arguably more conceptually sophisticated contemporary rival to it. With this, he raised the bar for social theory worldwide, from Germany, France, and Great Britain to Japan and even the former Soviet Union. A strong case can be made today that every major social theory since the mid-1960s has been developed in direct or indirect dialogue with Parsons' functionalism (see Habermas 1981 for a related statement).

Having become literally an icon in the discipline in the first three decades of his career, in the last two decades he attracted a considerable share of the iconoclasm that more generally characterized the student movement and academia of the late 1960s and early 1970s. Parsons was subject across two decades to far greater criticism than that directed to any other theorist of his generation or since. Given the tenor of the times, most criticisms were rhetorical, often personal. Today, they leave a strong impression that few critics had bothered to read his works with the care typically afforded to basic empirical studies, let alone with the rigor and dispassion that any complicated social theory demands. Yet, the cumulative effect of the broadsides he received in the late 1960s and early 1970s was to leave the collective memory of the discipline with an understanding of Parsonian functionalism that is difficult to reconcile with often-repeated, explicitly-stated positions in his publications. What Parsons endeavored to accomplish in his day, providing the social sciences with a common language, and how he went about accomplishing it,

developing a ‘conceptual framework’ comprising analytical distinctions, now eludes the discipline’s collective memory.

Talcott Parsons was born on December 13, 1902 in Colorado Springs, the youngest of six children of Edward S. Parsons, a Congregational minister and college administrator, and Mary Augusta Ingersoll Parsons, a housewife and active suffragist (on biographical details, I rely primarily on Nielsen 1991). Both parents were New England WASPs who traced their ancestry to mid-eighteenth century settlers, Mary to theologian Jonathan Edwards. A graduate of Yale Divinity School, Edward Parsons holds fundamentalist views of Christianity but leftist views in politics, particularly regarding the issue of economic inequality. He is an active participant in the Social Gospel movement that supported organized labor. Both parents inculcate into Talcott and his older siblings the importance of finding a mission in life and then pursuing it assiduously. Many observers comment later on the mature Talcott’s remarkable energy and perseverance—including on the final two days of his life in Munich in 1979. He published over 150 sole-authored articles and 14 books or collections.

In 1917 the Trustees of Colorado College force Edward to resign as Dean after he supports two women who charged the College’s President with sexual harassment. The family then moves to New York City where Talcott enters Horace Mann High School, a laboratory school for boys operated by Teacher’s College of Columbia University. Talcott earns an undergraduate degree at Amherst College (as had his father and two older brothers) from 1920–4. At the time Amherst was also an experimental, progressive school. Parsons at first focuses on biology and chemistry but in his junior year becomes ‘converted’ to the social sciences under the influence of an unorthodox institutional economist, Walton Hamilton.

Parsons’ graduate training was remarkably brief: one academic year (1924–5) at the London School of Economics as a nondegree candidate, then another (1925–6) as a degree candidate at Heidelberg University. At LSE, Parsons was influenced by Morris Ginsberg, L. T. Hobhouse, and the methodological functionalism of anthropologist Bronislaw Malinowski—as well as by fellow-student E. E. Evans-Pritchard. Parsons also met his future wife and mother of three children, Helen Banerott Walker, a Bryn Mawr College student studying banking. Her family of conservative white- and blue-collar workers consider Talcott a leftist, a ‘pinky.’ At Heidelberg, Parsons first learnt of the recently deceased German social theorist Max Weber and discussed his work with his wife Marianne, his younger brother Alfred, and Alexander von Schelting. Taking coursework from Edgar Salin and Emil Lederer (on economics), Karl Mannheim (a friend of Georg Lukacs) and Karl Jaspers (on Kant), Parsons selected how sociology and

economics differ in portraying ‘capitalism’ as his dissertation topic.

During his year at Heidelberg Parsons was offered a one-year teaching appointment at Amherst in the Economics Department which also allowed him to teach an independent course in sociology. In 1927 Parsons was offered an instructorship in economics at Harvard, thus beginning a life-long career there. Harvard’s Department of Sociology was a relative late-comer in the discipline, beginning in the fall 1931 under the chairmanship of Pitrim Sorokin, a 42-year old emigre from Russia recruited from University of Minnesota. Parsons, then 29, was appointed as an instructor. Disagreements and misunderstanding between the two theorists became common knowledge in the Department and across the University. Yet, throughout Parsons’ career, both critics and proponents often commented on his low-key demeanor when grappling with ideas and interacting with colleagues and students. It is difficult to find accounts of him being particularly effusive, let alone dominating. A short, stocky, already balding young man who sports a moustache and always smokes cigarettes, critics also comment often on his charm when interacting with other major national and international academicians at Harvard, in the American government, and overseas.

During his earliest years at Harvard, Parsons was impressed with philosopher Alfred North Whitehead and his notion of the ‘fallacy of misplaced concreteness.’ Consistent with Kant, Whitehead held that scientists apprehend ‘reality’ or scientific ‘truth’ only through analytical distinctions, not more immediately—whether experientially or directly through empirical findings. A few years later in correspondence with phenomenologist Alfred Schutz from 1940–1, Parsons defended the notion of ‘analytical realism’—as opposed to ontological realism or empirical realism—against Schutz’s position that social scientists can somehow gain more direct access to the ‘life-world’ of their subjects of study (Grathoff 1978).

By contrast to Schutz and then also to ethnographers at University of Chicago and American empirical researchers more generally, Parsons endeavored across his 50-year career to identify the most irreducible analytical distinctions unique to sociology, the scientific study of social life. In pursuing this project, Parsons arrived at three successive ‘theoretical syntheses’ and along the way trains four remarkably talented and productive cohorts of graduate students. All three of Parsons’ theories, which he called ‘frameworks of concepts,’ involve a ‘functionalist’ approach to the study of social life. This is an approach much maligned today, and yet a basic premise of functionalism is hardly controversial. Any social scientist who poses the following question is operating within a functionalist approach: What is the relationship, if any, between the substantive area of social life I am studying and the direction of social change? Here,

then, is a common ground shared by critical theorists and Parsonian functionalists but not by more historicist researchers, those who study particular events or periods in isolation and are loathe to identify any direction of social change.

While exceedingly abstract and complex, there are two ways to grasp the significance of Parsons' publications across his career. In general, he endeavored to account for the place and purpose of norms in maintaining social order both historically and cross-nationally. More particularly, he endeavored to account for the place and larger significance of professions, a unique set of occupations, in contemporary societies. Professions are a pivotal subject for sociological inquiry because they are important nongovernmental bodies in all modern societies. Yet, their prestige or status in any society hinges as much on whether they are valued culturally, supported by generally recognized social norms, and centrally situated in a social structure as on whether practicing professionals compete effectively in self-regulating markets. In all modern societies, professionals are simultaneously driven by economic pressures to maximize profits, like other workers, and also by normative pressures to conform to certain extra-economic standards of conduct that typically do not bind most other workers. Parsons was interested in accounting at a theoretical level for the rise, evolution, and institutionalization of these extra-economic restraints on self-interested behavior, and then also to explore whether and how they contribute to social order.

In his earliest publications, from the 1920s to the mid-1940s, Parsons approached professions by first distinguishing their behavior from that of economic enterprises, on one side, and religious organizations, on the other. Corporate managers and shareholders tend to act in strictly utilitarian or market-mimicking ways as they endeavor to maximize either growth or profit, a quantitative end that can be recognized interpersonally. Clerics and religious believers, however, tend to exhibit ritualistic fidelity to norms as they—presumably—seek spiritual salvation. This is a qualitative end that is transcendental or metaphysical; as such, its attainment is a matter of faith, not something that can be recognized interpersonally. Professionals, Parsons held, also exhibit fidelity to norms, but more 'voluntaristically.' They do not act in strictly market-mimicking ways, but they also do not conform to norms ritualistically with any transcendental end in view. Rather, they exhibit fidelity to norms as a means to attain qualitative ends that are worldly or empirical, and thus capable of being recognized interpersonally—such as their patients' physical or mental health, or their clients' legal innocence, or scientific truth.

Parsons came to appreciate the significance of 'voluntaristic action' after a careful reading of two economic theorists, Alfred Marshall and Vilfredo Pareto, and two social theorists, Emile Durkheim and

Max Weber. This reading forms the core of *The Structure of Social Action* (1937) which, along with Parsons's 1930 translation of Weber's *The Protestant Ethic and the Spirit of Capitalism*, established Weber and Durkheim as two of the new discipline's 'classic' theorists. During the 1930s, Parsons trained a first cohort of graduate students in the classics and his own theory of 'voluntaristic action,' including: Robert Merton, Kingsley Davis, John and Mathilda Riley, Edward Devereux, Marion Levy, Wilbert Moore, and Florence Kluckhohn (along with Edward Hartshorne who was killed by a sniper while on active service in postwar Germany).

In spring 1944 Parsons was promoted to full professor and the chairmanship. By January 1946, he transformed the Department of Sociology into the Department of Social Relations, with the explicit aim of linking structural and social psychological approaches in the scientific study of social life. In the same year, Parsons also began formal training in psychoanalysis as a Class C candidate at the Boston Psychoanalytic Institute. He had been lecturing informally on Freud since fall 1938.

As Parsons assumed his leadership role in Harvard's Department, his theory went through a brief mid-career change from the late 1940s to the mid-1950s as he considered findings from Robert Bales's study of small groups. Parsons began thinking about professions (and how to identify norms in social life more generally) in terms of six basic decisions that people performing any role or task either make explicitly or have imposed on them by cultural values, institutionalized norms, or social structures. For example, certain roles (including those performed by professionals) mandate treating others (clients or patients) in universalistic ways. By contrast, other roles (including those performed by parents) encourage more particularistic treatment of others (children). Parsons called these decisions and requirements 'pattern variables.' By his account, researchers can use six such variable-pairs (a) to distinguish professions from other occupations and (b) to identify changes in the behavior of professions both historically and cross-nationally. Parsons' major publications during this period are a collection, *Essays in Sociological Theory Pure and Applied* (1949), and three monographs: *The Social System* (1951), *Towards a General Theory of Action* (1951, with Shils), and *Working Papers in the Theory of Action* (1953, with Robert Bales and Edward Shils).

During this period Parsons trained a second cohort of graduate students in the pattern variables, including: Bernard Barber, Harry Johnson, Robin Williams, Jr., Jesse Pitts, Harold Garfinkel, Francis Sutton, and Robert Bales. More generally, as part of the buoyancy and optimism that pervaded the US after the war, many sociology departments re-evaluate their curricula. The discipline is open collectively to receiving a new theoretical synthesis, and Parsons' notion of pattern variables, while preliminary and as it

turned out fleeting, is a prime candidate. Another is Robert Merton's notion of 'middle range theory,' an idea he first proposed at the annual meeting of the then American Sociological Society in 1947 in opposition to Parsons' 'general theory.'

Finally, beginning slowly in the mid-1950s and then with more rapid developments from the early 1960s to the end of his career, Parsons approached professions within what he called the 'AGIL schema.' This is Parsons' single most significant contribution to social theory. During his transition from the pattern variables to the AGIL schema, Parsons' publications, lectures, and presentations create an unusually kinetic intellectual excitement among collaborators and graduate students. Everyone working in his circle operated with a palpable sense that social theory is in the midst of a fundamental breakthrough, a sense that American sociology has not witnessed since.

This transition period to Parsons' mature social theory is marked in particular by *Economy and Society* (1956, with Neil Smelser), and Parsons' training of a third cohort of graduate students, including: Albert Cohen, Renee Fox, Joseph Berger, Norman Birnbaum, Neil Smelser, James Olds, Jackson Toby, and Miriam Johnson. In addition, many earlier graduate students whose training had been interrupted by wartime service returned to Harvard. Talented undergraduates who come into contact with Parsons during this period include Robert Bellah and Charles Tilly. Also in transition during this period is the leadership of sociology at Harvard. Parsons resigns as chair of the Department of Social Relations in 1956, and within the next two years learns that he has diabetes. Sorokin retires in 1959.

From 1956 to 1961, Lewis Coser and Dennis Wrong in the US, David Lockwood in Great Britain, and Ralf Dahrendorf in Germany challenged Parsons' functionalism in relatively measured tones, but with uneven rigor. They were also shooting at a moving target in that Parsons was developing his mature social theory. The high-point of scholarly criticism during this period comes with a collection of essays by philosophers and sociologists edited by Max Black, to which Parsons responded with a long concluding chapter. In April 1964, Parsons was a central figure at a famous session of the German Sociology Association in Heidelberg devoted to reconsidering Max Weber's contributions. He found himself at odds with Frankfurt School critical theorists, most notably the young Jürgen Habermas and the more established Max Horkheimer and Herbert Marcuse (see Stammer 1965/1972 for a collection of these exchanges).

From this point forward, criticisms of Parsons become harsher, more personal and ideological than analytical and scholarly. Parsons was attacked, particularly in the US, for: his religious background, his WASP ethnic and cultural heritage, his writing style, his amazing productivity, his putatively strategic rather than scholarly decision to make sociology as

rigorous conceptually as economics, his putative mistranslation of Weber, the putative conservative nature of his own family life including his putative responsibility for his daughter's suicide (in June 1964, two weeks after the Heidelberg debate), his putative political conservatism, and his putative general obedience to 'American capitalism' or 'the establishment.'

Parsons unveiled the AGIL schema explicitly in 1963, with major articles on the concepts of power and influence, and then in 1964, with his first statement about 'evolutionary universals' (see the Turner 1999 collection for the 1964 article and references to the others). As fully developed, the AGIL schema isolates analytically those aspects of behavior in any role or position that contribute, respectively, to each of four general social 'functions': economic efficiency ('adaptation'), administrative effectiveness ('goal-attainment'), fidelity to social norms ('integration'), and fidelity to cultural values or a society's most basic institutional arrangements ('latency'). Parsons also proposed that four 'media of interchange' circulate between these analytical subsystems—money, power, influence, and value commitments—thereby bringing a certain orderliness or predictability to the whole. He added notions of 'systems-theory,' 'pattern maintenance,' and 'hierarchy of control' to this basic four-function breakdown of social life.

In 1973, Parsons and Platt published what is arguably his most important single work since 1937, *The American University*. In this work Parsons re-thinks his approach to professions by incorporating two major points into his social theory. First, he proposes that professions and sites of professional practice (such as universities, hospitals, and research institutes) are organized in a 'collegial form,' not in a bureaucratic form or a democratic form. Second, he proposes that professions are distinguished from other occupations by their members' willingness to bear 'fiduciary responsibilities' to clients and the larger society. These two points provide the foundations for an account of the place and purpose of professions in contemporary societies that differs radically from any effort, whether by rational choice theorists or social critics on the left, to treat the professions analytically as interchangeable with other occupations or other corporate entities. By 1973, however, the collective memory of the discipline is so dominated by criticisms of the AGIL schema that this major work, arguably Parsons' single most important substantive contribution to social theory, goes largely unread by critics and proponents alike.

Through the 1960s and 1970s, Parsons trained a fourth and final cohort of graduate students in the AGIL schema and related theoretical developments, including: Victor Lidz, Jan Loubser, Leon Mayhew, Rainer Baum, Dean Gerstein, John Akula, and Willy DeCramer. Parsons also influences undergraduate Jeffrey Alexander. Only in the mid-1970s, a few years before his death, did Parsons begin methodically to

respond to at least a few criticisms of his work, most notably the informed analyses of Bershadsky (1973) and Warner (1978). Bershadsky's *Ideology and Social Knowledge* in particular marks a major sea change in commentary on Parsons' works. Bershadsky is the first to draw attention to Parsons' effort to ground the social sciences against relativism with analytical concepts. More than anyone else Bershadsky appreciates that Parsons pitched his social theory at an unusually abstract level of analysis because he sought literally a common language for the social sciences. Prior to Bershadsky both proponents and critics generally failed to convey the power and sweep of Parsons' social theory in form, its aspiration to unite the social sciences. Parsons' project was essentially to give structuralists and symbolic interactionists the means, the common language, by which to demonstrate to each other the central import of their respective findings.

Parsons demonstrated his capacity to 'translate' others' findings and ideas in his own scholarship. He co-authored, team-taught, or otherwise collaborated closely with a remarkable range of theorists and researchers across disciplines, including: Edward Shils, Joseph Schumpeter, Samuel Stouffer, Florence Kluckhohn, Robert F. Bales, James Olds, Morris Zelditch, Philip Slater, Neil Smelser, Lon Fuller, Kaspar Naegle, Jesse Pitts, Winston White, S. N. Eisenstadt, Robert Bellah, Victor Lidz, Gerald Platt, Edward Laumann, Erwin Scheuch, Andrew Effrat, Mark Gould, and Dean Gerstein. In addition, he engaged in private and public correspondence and debates with Frank Knight, Crane Brinton, Robert Bierstedt, Albert Blumenthal, Alfred Schutz, Chester Barnard, Philip Selznick, Eric Voegelin, Robert Merton, Kenneth Boulding, C. Wright Mills, Robert Bellah, Bennett Berger, David Riesman, Jurgen Habermas, Herbert Marcuse, Max Horkheimer, and Ernest Mayr. Finally, an impressive set of scholars was influenced heavily by Parsons himself, his students, or his theory (some of whom also influence Parsons and his students): Niklas Luhmann, Seymour Martin Lipset, Amitai Etzioni, Robert Marsh, Daniel Bell, Joseph Ben-David, Benjamin Nelson, Gabriel Almond, James S. Coleman, Karl Deutsch, David Apter, Lucian Pye, Sidney Verba, Chalmers Johnson, S. N. Eisenstadt, Ken'ichi Tominaga (Japan's leading postwar sociologist), Lawrence Brownstein, Martin Martel, Adrian Hayes, and Frank Lechner.

Parsons and Helen travelled frequently in the 1970s, including three separate trips to Japan. In early May 1979 they returned to Heidelberg, then proceeded to Munich, on the occasion of the fiftieth anniversary of Talcott's degree from Heidelberg. After Parsons' typical full day of presentations and scholarly exchanges, including a lecture on 'The Declining Significance of Social Class' attended by host Horst Helle as well as Jurgen Habermas, Niklas Luhmann, Richard Munch, and Wolfgang Schluchter, Parsons died of a stroke in the early hours of May 8. At a

memorial service 10 days later in Harvard Chapel, Victor Lidz notes in eulogy: 'No sociologist of recent times has had to endure more bitter criticism than Talcott. Although a passionate man, Talcott bore criticism with equanimity as well as courage. Not daunted by even sweeping attack, he held to his own program of research and writing. Moreover, adhering to principles of value-freedom, he declined to reciprocate ideological criticism. He dealt with criticisms, always, as technical matters within the domain of social scientific theory' (Nielsen 1991).

Parsons' critics inadvertently encouraged the fragmentation of research and theory in sociology and the social sciences that Parsons endeavored to prevent. Today, in the absence of any shared framework of analytical concepts, social scientists routinely talk past each other, as opposed to revealing to each other the general importance of their research findings and theoretical developments. Parsons's 'general theory' has given way not to a finite set of readily identifiable theories of the 'middle range,' as Robert Merton anticipated in 1949, but rather to an ever more finely grained cacophony of research specialties. This trend is then recapitulated, and accelerated, by ongoing changes in graduate training. Graduate students are trained more and more narrowly, and their required survey courses in social theory hardly encourage them to move beyond any research specialty. If there is any 'common language' in the social sciences today, it is that of research methods. But even here there is more internal division among methodologists than they often wish to acknowledge.

In support of Habermas' point that we can expect any new theoretical development in the social sciences to respond directly or indirectly to Parsons' functionalism, French social theorist Pierre Bourdieu in many regards today recapitulates Parsons' AGIL schema. He identifies two poles within what he calls 'fields of power'—the economic field and the field of cultural production—and then distinguishes four fields in between: politics, the higher civil service, the professions, and the university (Bourdieu 1989/1996). The major difference with Parsons is that the French theorist's categories are more directly descriptive, less analytically rigorous. As a result, it is not clear on what basis he is distinguishing fields, why there are six fields of power rather than four or eight, or on what basis researchers may categorize particular groups or activities as components of one field or another.

By the early 1980s, a new generation of social theorists, including members of Parsons' last cohort of graduate and undergraduate students at Harvard, initiated the effort to have Parsons' publications reconsidered on scholarly grounds. Led initially by Munch (1981) in Germany and Alexander (1983, 1985) in the US, today's 'neofunctionalism' finds support from theorists whose political positions range from radical left to liberal reformist to conservative republican (see the collections edited by Hamilton 1992

and Colomy 1990). What they share, with Parsons himself, are two general principles (which Alexander 1988 now explicitly rejects). One is that it is vitally important to the social sciences to continue Parsons' effort to ground social theory on the basic analytical distinctions of the AGIL schema rather than to rely more directly on descriptive concepts (whether empirical generalizations or ideal types). The other principle is that it is incumbent today to demonstrate the empirical potential of Parsonian functionalism, to identify lines of empirical inquiry that this social theory uniquely presents to view (Sciulli 1992). A strong case can be made that Parsons' social theory has been mined only superficially (Takagi in press). An equally strong case can be made that theorists and researchers today can draw fruitfully on Parsons' basic AGIL schema, and then the first set of subdivisions he drew within each 'function,' but that they need not follow Parsons' effort to draw further distinctions within each subdivision (Mouzelis 1995).

Social theorists outside the US today who support the Parsonian tradition, even if critical of certain parts of it, include: Munch, Hans Joas, Uta Gerhardt, Horst Helle, and Harald Wenzel in Germany; Helmut Staubmann in Austria; Jens Kaalhaug Nielsen in Denmark; Pierpaolo Donati, Andrea Maccarini, Matteo Bortolini, and Riccardo Prandini in Italy; Ken'ichi Tominaga, Kiyomitsu Yui, and Kazuyoshi Takagi in Japan; and Nicos Mouzelis, Bryan Turner, and Jeremy Tanner in Great Britain.

Partial Orders

The idea of ordering captures a basic faculty of the human mind: to decide for two given elements from a set of objects which one 'dominates' the other with respect to an attribute of interest, or, alternatively, which one is 'preferred' to the other.

Formally, a partially ordered set (a poset for short) consists of a pair $(P, \leq)$ where P is a nonempty set and $\leq$ a binary relation on P satisfying for all $x, y, z \in P$:

- (a) reflexivity: $x \leq x$,
- (b) asymmetry: $x \leq y$ and $y \leq x$ implies $x = y$,
- (c) transitivity: $x \leq y$ and $y \leq z$ implies $x \leq z$.

Transitivity is, in a sense, the most important property; it is shared by all variants of order relations, though it might be a consequence of other conditions. However, asymmetry also contributes in an essential way to the meaning of a partial order. Reflexivity, on the contrary, is merely a matter of taste or con-

venience. In some cases its opposite, irreflexivity, is postulated. Such an order is called *strict*. If the asymmetry condition is replaced by symmetry, i.e., for all $x, y \in P$ $x \leq y$ implies $y \leq x$, then the resulting structure is an equivalence relation which lacks the interpretation of ‘dominance’ or ‘preference.’ Such a structure is more akin to classification or grouping with respect to similarity.

1. Related Notions and Diagrams

Sometimes asymmetry is simply dropped from the conditions. A relation satisfying reflexivity and transitivity is called a *quasiorder*. The investigation of quasiorders can be split into the respective properties of a partial order and an equivalence relation in the following way: Let $(Q, \lesssim)$ denote a quasiorder. Define $x \sim y$ if $x \lesssim y$ and $y \lesssim x$ both hold true. Then it is readily shown that $\sim$ is an equivalence relation on Q . Let P be the set of equivalence classes and define for $p, q \in P$ the relation $p \leq q$ if $x \lesssim y$ for some $x \in p$ and $y \in q$. Then, one demonstrates two things: first, that the definition of $\leq$ is independent of the particular elements $x \in p$ and $y \in q$; and second, that $(P, \leq)$ is a poset. Thus, the ‘dominance-aspect’ of a quasiorder is contained in $\leq$, and its ‘classification-aspect’ is hidden in $\sim$.

One property of an intuitive meaning of dominance is not captured in the notion of a partial order: the idea that any two elements can be compared with respect to $\leq$. The defining conditions of a poset do not imply connectivity, i.e.,

$$x \leq y \text{ or } y \leq x \text{ for all } x, y \in P.$$

(Note: often this property is called ‘completeness,’ but later in this article another notion of completeness is introduced). If connectivity is added to the properties of a partial order $(P, \leq)$, then $\leq$ is called a linear or total order. A quasiorder satisfying connectivity is called a weak order. Applying the above procedure on a weak order results in a linear order on the equivalence classes of the weak order.

There is a tendency to associate the property of connectivity automatically with an order given in some field of application, e.g., if one rank orders stimuli or subjects. Doing this amounts to representing the order numerically, i.e., to assuming a function

$$f: P \rightarrow \mathbb{R} \text{ such that } x \leq y \text{ if } f(x) \leq f(y). \quad (1)$$

If such a representation is possible, the order is necessarily a weak order. However, in social science, numerical representations are used widely even for orders which cannot easily be justified to be connected. For example, if the items of an achievement test are

Figure 1

The forbidden substructures of a semiorder

Figure 2

Lattices (b, c, e) and non-lattices (a, d)

‘Rasch-scaled’ (see the discussion following Eqn. (3)), a difficulty coefficient is attached to each item. This numerical scale orders the items weakly and ascribes the often made observation that subjects solve a difficult item correctly and fail at an easier one to influences of chance and error. This interpretation appears so obvious that its proponents tend to overlook the *petitio principii* which it entails, that the difficulty of an item is defined by the numerical parameter, whereas the weak ordering of the items according to a material notion of difficulty is an empirical property which will in many cases not be fulfilled.

For example, an expert judging this might well regard some items as incomparable. In such a situation a partial- (or quasi-)ordering, which allows for incomparable items, is more flexible. Thus, the assignment of numerical values, albeit ubiquitous in psychological tests, restricts drastically the range of possible models. Even partial orders can be too restrictive because transitivity is also a strong condition. The theory of knowledge spaces takes account of this aspect (see *Knowledge Spaces* for a deeper treatment of these issues).

The most convenient way of representing a poset is by its (*Hasse*) *diagram* (see Figs. 1 and 2). To construct it, one first defines $x < y$, in words ‘ y covers x ,’ to mean: $x < z \leq y$ implies $z = y$. Next, one draws a graph in which the vertices correspond to the elements of P , two elements are connected by an edge if one of them covers the other, and furthermore the covering element is placed above the horizontal line determined

by the covered element. Hasse diagrams are easy to draw and are of great help in theoretical considerations as well as in interpreting empirical findings.

2. Special Classes of Orders

There are numerous specializations, that is, additions of further properties, such that the resulting structure is something in between a poset and a linear order. In this section, two classes are considered which have useful numerical representations, although not the strong one of Eqn. (1). The third specialization considered here, namely lattices, is important because it tends to bridge the gap between ordering relations and algebraic operations.

2.1 Semiorders

In psychophysics one has to deal with the phenomenon of subliminal changes in intensity of physical stimuli. One stimulus may be (physically) slightly more intense than another, but a subject does not perceive the difference. For example, one might imagine a coffee-taster confronted with an extended series of cups of coffee, each with one more grain of sugar than its immediate predecessor. He/she will probably not notice the difference in taste between successive cups, but surely the difference between the first and the last cup will be clearly noticeable. In other words, indifference with respect to $\leq$ is not transitive. Similar observations can be made in decision theory and other branches of psychology. One way of describing such facts is to introduce sensory thresholds, thereby creating a scaling problem where one wants to scale both the subjective intensity and the magnitude of the threshold. Luce (1956) considered two conditions which seem plausible in this context (P is the set of stimuli and $x \leq y$ denotes the observation x is less intense than y):

(S1) If $x \leq y$ and $u \leq v$, then $x \leq v$ or $u \leq y$.

(S2) If $x \leq y \leq z$ and $w \in P$, then $w \leq z$ on $x \leq w$.

One easily shows that $(P, \leq)$ is a quasiorder, i.e., without losing generality, one can assume that it is a partial order. Condition (S1) says that it does not contain Fig. 1(a) as a suborder. Similarly, condition (S2) is equivalent to the fact that it does not contain Fig. 1(b) as a suborder.

From the viewpoint of measurement the most important property of semiorders is the possibility of a numerical representation with a constant threshold. More precisely, one can show that for a finite semiorder $(P, \leq)$ there is a function f

$$f: P \rightarrow \mathbb{R}: \text{ such that } x < y \text{ if } f(x) + 1 < f(y). \quad (2)$$

The condition of finiteness is far too restrictive for Eqn. (2), but without further restrictions it does not obtain. The height of the threshold is arbitrary, that is, the number one in Eqn. (2) can be replaced by any other positive number (with a rescaled f). More on this kind of representation theorem can be found in Roberts (1979, Chap. 6.1) or Suppes et al. (1989, Chap. 16). Clearly, the converse of this theorem is true: a structure with a representation, Eqn. (2) is necessarily a semiorder.

Although the semiorder concept seems to have its origin in the psychological context of the possibility of measurement of subjective intensity described above, it is now a well-established notion in the mathematical theory of posets and several remarkable results are connected with it. Some of them are mentioned in the following text.

2.2 Interval Orders

A structure satisfying only condition (S1) but not necessarily (S2) is called an interval order. This notion derives from the numerical representation which is characteristic of this kind of order. Each element can be represented by an interval on the real line and $x < y$ or $y < x$ is tantamount to the nonoverlapping of the respective intervals. Put another way, a scale value and a threshold are attached to each element, but the height of the threshold can vary in contrast to Eqn. (2). The reader will find many interesting properties and proofs in Fishburn (1985).

Historically, it is of interest that, although the representation theorem is due to Fishburn (1970), the investigation of this structure goes back to papers of Norbert Wiener, early, in the twentieth century. What is even more remarkable is that in this work he mentioned possible applications in experimental psychology (see Fishburn and Monjardet 1992).

The theory of interval orders has applications in archeology in connection with the seriation problem. In this case P is a set of artifacts, each element of which was some time in use. From excavations in various historical sites it is known for any two artifacts whether the period of use of one follows that of another with or without overlap. If this relation satisfies (S1) then, by the interval order representation theorem, it follows that it is possible to assign a time interval to each artifact, preserving the empirical observations.

A related notion is that of a biorder. The primitives of a biorder consist of two sets P and Q and a relation ρ between P and Q , i.e., a subset $\rho \subseteq P \times Q$ satisfying for all $x, y \in P$ and $u, v \in Q$

$$x\rho u, y\rho v, \text{ implies } x\rho v \text{ or } y\rho u. \quad (3)$$

To understand this condition, it is helpful to think of P as a set of subjects and of Q as the items of an

achievement test. xpu means ‘subject x fails to solve item u .’ The premise of Eqn. (3) says that x fails u and y fails u : if one assumes that x solves v correctly, then y has to fail u . With this interpretation, the biorder concept is the basis of Guttman scaling. Probabilistic modifications of it underly Rasch scaling, which is well-established in the theory of psychological tests. Thus, with the biorder condition Eqn. (3), a testable property is formulated which, when satisfied, justifies a numerical difficulty value for items because a numerical representation of a biorder consists of two functions $f: P \rightarrow \mathbb{R}$ and $g: Q \rightarrow \mathbb{R}$ such that:

$$xpu \text{ if } f(x) < g(y).$$

This, in turn, implies Eqn. (3). In the terminology of the above interpretation of a biorder $f(x)$ is the ability of subject x and $g(u)$ is the difficulty of item u . If in a biorder, the two sets coincide, $P = Q$, then Eqn. (3) reduces to (S1), i.e., the structure is an interval order.

2.3 Lattices

In a partial order $(P, \leq)$ subsets of P may or may not have upper or lower bounds, where upper bounds are elements which dominate all elements of the subset and lower bounds are elements which are dominated by all its elements. If each two-element subset has a unique smallest upper bound—called the supremum—and a unique greatest lower bound—called the infimum—then the structure is called a lattice. The infimum of x and y is denoted by $x \wedge y$ and the supremum by $x \vee y$. Examples of lattices and non-lattices are given in Fig. 2.

Further examples are the power set of a set ordered by set inclusion, any subset of the reals naturally ordered, and the natural numbers $\{1, 2, 3, \dots\}$ ordered by divisibility, i.e., $m \leq n$ if m divides n . In the last example, the least common multiple and the greatest common divisor are the supremum and the infimum, respectively. It follows easily by induction that any finite subset of a lattice P has an infimum and a supremum. However, infinite subsets do not necessarily have this property. If all subsets of P have it, then the lattice is called complete. Thus, finite lattices are always complete, but the rationals with the natural ordering are not. The question of completion of lattices similar to the construction of the reals by Dedekind cuts is discussed in Sect. 5.

There is a more algebraic way of characterizing lattices, where infimum and supremum are regarded as binary operations on P :

Theorem 1 Let $(P, \leq)$ be a lattice. Then for all $x, y, z \in P$:

$$(a) \quad x \vee (y \wedge z) = (x \vee y) \wedge z \text{ and } x \wedge (y \vee z) = (x \wedge y) \vee z$$

$$(b) \quad x \vee y = y \vee x \text{ and } x \wedge y = y \wedge x$$

$$(c) \quad x \wedge (x \vee y) = x \text{ and } x \vee (x \wedge y) = x.$$

Conversely, if a structure $(P, \vee, \wedge)$ is given with operations $\vee, \wedge$ satisfying the conditions (a), (b), and (c), then $\leq$ is defined by

$$x \leq y, \text{ if } x \wedge y = x$$

is a partial order on P such that $(P, \leq)$ is a lattice.

Lattices play an important role in pure and applied mathematics. John von Neumann, one of founders of lattice theory, developed his formulation of quantum mechanics in terms of lattices. Today they are used in many branches of mathematics—for instance, in combinatorics, probability theory, logic, and functional analysis. The wide applicability of lattices in technical and social science contexts is best demonstrated by the development of ‘concept analysis’ by Rudolf Wille (see Ganter and Wille (1996).

3. Extension of Orders; Szpilrajn’s Theorem

Is it possible to extend a partial order by adding (x, y) or (y, x) to $\leq$, when x and y are incomparable in $\leq$ and at the same time keeping the extended relation a partial order? Is it possible to extend $\leq$ to a linear order in this way? Both questions are answered in the affirmative by the following theorem.

Theorem 2 (Szpilrajn’s Theorem) Let $(P, \leq)$ be a poset and $x, y \in P$ such that neither $x \leq y$ nor $y \leq x$. Then there are two linear orders $\leq'$ and $\leq''$, each of which contains $\leq$ as a subset, and such that $x \leq' y$ and $y \leq'' x$.

The proof of this theorem is not difficult for finite P , but entails a set theoretic twist in the infinite case. If x and y are incomparable in $\leq$ then one defines $x \leq' y$, adds all pairs to $\leq'$ which this choice and transitivity forces and goes ahead until no incomparable pairs are left over. The latter step of this argument is a bit of a problem for an infinite P .

Sometimes one can regard a partial order as ensuing from incomplete data collection, incomplete in so far as a linear order can be expected, but the available data give only a part of the full order information. Then the question of a linear extension is relevant, in particular, one can ask how many additional pairwise comparisons must be performed to obtain the full linear order, which is the most parsimonious way to find such an extension.

For these problems the number of linear extensions is of importance. It was shown by Fishburn and Trotter (1992) that for all partial orders with fixed $|P| = n$ and k pairs in $\leq$ those with a maximal number of linear extensions are semiorders. For $k \leq n$ these semiorders are characterized, but for larger K there seem to remain several unsolved problems.

It can be shown that a linear extension can be found with at most K questions of the form ‘is x larger than

y , where K is of the magnitude of the logarithm of the number of linear extensions (see Trotter 1995 for details). In connection with this problem it seems that a pair x, y for which many extensions with $x \leq y$, as well as many with $y \leq x$ exist is best to investigate first because, whatever the answer, it considerably reduces the number of data which remain to be collected. In this context the so called 1/3–2/3 conjecture was made. It says that each poset which is not a linear order contains a pair (x, y) for which the relative frequency of extensions with $x \leq y$ is between 1/3 and 2/3. This conjecture seems still open. However, bounds are known, e.g., the relative frequency is between 3/11 and 8/11. The proof of this result draws on a geometric inequality and is extremely beautiful. For semiorders the 1/3–2/3 conjecture is true. More on this topic and some of the proofs can be found in Trotter (1995).

4. Order Dimension

A corollary of Szpilrajn's Theorem is that each partial order is the intersection of its linear extensions. One can ask for the minimal number of linear extensions with this property and regard this number as a measure of complexity of the order. It is called the dimension of $(P, \leq)$.

All orders on three, four, and five elements are two-dimensional (provided they are not linear). There are two orders with six elements of dimension three. One can group the posets in classes of increasing dimension. The semiorders have a dimension less than or equal to three, but the interval orders can have arbitrary large dimension.

One classical result on the dimension is that it is always smaller than or equal to the maximal number of pairwise incomparable elements. For $|P| \geq 4$ ($|P|$ denotes the number of elements in P) the dimension is bounded above by $|P|/2$ and this is the best possible solution. It is an active area of research to find inequalities such as these which relate the dimension to other characteristics of the poset (see Trotter (1992)).

There are other variants of the dimension concept: one can replace linear orders by semiorders (and obtain the semiorder dimension) or by interval orders or by any other class of partial orders. For biorders, see Doignon et al. (1984) and Koppen (1987). These two papers attempt to link this dimension concept to techniques of extracting factors to explain data. In this way, an ordinal factor analysis is outlined. Factor analytic procedures used to be widely spread in social science research, but until now they seem to lack a sound axiomatic foundation. The order theoretic dimension concept can provide a weaker concept of a factor which is, on the other hand, much easier to justify, or empirically to test for adequacy.

5. Embeddability and Completion of Orders

Sometimes the nonexistence of suprema and infima is a nuisance; just think of the inconvenience caused when a sequence of rational numbers 'converges,' but the limit does not exist (in the rationals). One tries to avoid this situation by embedding a given poset into a complete lattice which contains the original order as a suborder. In contrast to the techniques in Sect. 3, one adds new elements to P instead of new pairs to $\leq$. Thus, the aim is to find a superstructure which resembles the given order as closely as possible, but which can be handled more conveniently because of the existence of suprema and infima. The prototype of this kind of extension is the time-honored construction of the reals from the rational numbers.

To begin with, some notation must be introduced. For $X \subseteq P$ let:

$$X^\vee := \{y \in P: y \leq x \text{ for all } x \in X\}$$

$$X^\Delta := \{y \in P; x \leq y \text{ for all } x \in X\}.$$

Thus $X^\vee$ is the set of lower bounds of X and X^Δ the set of upper bounds of X . The sets $\{x\}^\vee$ and $\{x\}^\Delta$ for $x \in P$ are abbreviated by $x^\vee$ and x^Δ , respectively. One simple way of embedding consists of considering

$$\nabla_{(P, \leq)} := \{x^\vee; x \in P\}$$

the so called principal ideal representation. Note that $(\nabla_{(P, \leq)}, \subseteq)$ is a suborder of the complete lattice of the power set, isomorphic to $(P, \leq)$. However, this embedding is not sufficient for the purposes of this section; the superstructure carries too little information from the original one. Therefore, a more parsimonious extension must be constructed.

To this end, a pair (X, Y) is called a MacNeille cut if and only if $X = Y^\vee$ and $Y = X^\Delta$. The set of all MacNeille cuts is a better candidate for an embedding. Indeed, one can prove:

Theorem 3 Denote by $C_{(P, \leq)}$ the set of all MacNeille cuts of a partial order $(P, \leq)$. Define for two cuts (X, Y) and (X', Y') the relation

$$(X, Y) \sqsubseteq (X', Y') \text{ if } X \subseteq X'.$$

Then $(C_{(P, \leq)}, \sqsubseteq)$ is a complete lattice. Moreover, it is the unique (up to isomorphism) smallest complete lattice which contains the original poset $(P, \leq)$ as a supremum dense subset, i.e., each element of $C_{(P, \leq)}$ is supremum of elements of $(P, \leq)$.

A few remarks should illustrate this theorem. First, the set corresponding to $(P, \leq)$ in $(C_{(P, \leq)}, \sqsubseteq)$ is the set of cuts $(x^\vee, x^\Delta)$. Second, if this theorem is applied to the rationals with the usual (linear) order, then the reals with added $\{-\infty\}$ and $\{\infty\}$ result as the MacNeille completion. The element $-\infty$ is the cut $(\emptyset, P)$ while ∞ is the cut $(P, \emptyset)$. Third, although the notion of a complete lattice only bears meaning for

infinite base sets P , the MacNeille completion makes sense also for finite posets. Figure 2(b) shows the MacNeille completion of (a) and Fig. 2(e) of (d). Finally, it is worth mentioning that the mappings $X \rightarrow X^\vee$ and $X \rightarrow X^\Delta$ form a pair of functions that are known as a Galois connection. This construction is often used when dealing with posets; it is applicable in other contexts, for example, formal concept analysis (see Ganter and Wille (1996) is based on a Galois connection). In this respect, concept lattices are a generalization of a MacNeille completion.

Participant Observation

Participant observation has been part of the arsenal of methodological techniques employed by social scientists since around 1900, notably within the discipline of sociology. Participant observation involves the active engagement of the researcher with the members

of the community that he or she wishes to study, typically as an equal member of the group.

This methodology falls under the general rubric of field research. It is important to recognize that there exist alternative styles of ‘field research’: a range of possibilities that this chapter will not cover. However, in contrast to the manner in which observational research has traditionally been conducted in anthropology, in sociology much ethnography is based on the assumption that the researcher is at least nominally a participant in the group being studied. Yet, the line that separates participant observation and other forms of ethnographic observation is uncertain and hazy, and for some scholars the two terms have been used as synonyms.

Since the mid-1970s there has been a notable increase in the frequency and the legitimacy of the variety of field methodologies within the social sciences. These qualitative, interpretive strategies, once considered ‘unscientific,’ have demonstrated their utility in a number of disciplines. That this occurred during a period in which social scientific funding was being decreased is surely no coincidence. Although at the beginning of the twenty-first century qualitative field methods do not have the same standing as quantitative methods (especially in psychology and economics), their growth is astonishing.

1. Advantages

Several distinct advantages justify participant observation; among these are the benefits of rich data, validity, *Verstehen*, and economy.

1.1 Richness

This methodology, in contrast to most methods that do not involve personal witnessing, provides for rich and detailed data. To investigate action, direct observation is essential. When this is coupled with the questioning of actors about their choices, tied to some measure of active involvement, the value of participant observation is evident. The form of data collection permits an intense depiction that produces a fullness of understanding.

1.2 Validity

A second benefit is analytical validity. Because the observations are of behavior *in situ*, the researcher can rely upon the claim that the findings are close to the ‘proper’ depiction of the scene. If the conclusions drawn from participant observation research are not always reliable, in that other investigators might reach different conclusions, they do reflect the belief that some aspect of the world as it ‘truly’ is, is being described.

1.3 Interpretive Understanding

Participant observation supports the demand of Max Weber to produce research that is characterized by *Verstehen* or a personal understanding. In this way participant observation with its emphasis on both participation and observation adds to research knowledge. By directly involving the researcher in the activity, one can understand on an immediate level the dynamics and motivations of behavior. The observer becomes other than an outsider. While research projects differ significantly on this dimension, involvement has advantages for a *verstehende* analysis that other approaches can not match.

1.4 Economy

Participant observation research is typically inexpensive. While this research strategy is surely labor-intensive, it is not capital-intensive. In many cases the researcher is the only member of the project, and can set the terms of his or her own involvement. Increasingly, however, team-research projects exist as well, and in these cases wages and benefits for hired observers may involve considerable costs. Yet, in the standard participant observation project the key resources consist of a technology for inscribing observations. Perhaps for reasons of cost, connected to the time and energy involved, participant observation has proven to be a technique most typically engaged in by scholars at the early stages of their academic careers.

2. Disadvantages

Just as there are significant advantages to this methodology, disadvantages are evident. Problems relate to proof, generalizability, bias, and time commitments.

2.1 Proof

Participant observation relies upon a single case study: the examination of one place. This raises questions about the nature of proof, or, put another way, about reliability. Will two researchers examining the same or similar social scenes reach the same conclusions? Often because of different perspectives upon entering the field and different experiences within the field, findings are sharply distinct. While the observations and interpretations of those observations may be compelling, one can reasonably wonder whether any set of conclusions is definitive.

2.2 Generalizability

Even if we accept the legitimacy of analyzing one scene, on what grounds can we generalize beyond that

setting? How far can our conclusions be pushed? Participant observation research has a problem in this regard because of the absence of scientific control that characterizes experimental research and produces confidence in the claim that important variables of social life have been adequately captured. As a result, the extent to which generalizability is legitimate is problematic in participant observation. Participant observers need to present a theoretical model that helps readers to judge the legitimacy of their broader claims in light of the audience's own experiences.

2.3 Bias

A strength of participant observation methodology is that the researcher's insight and perspective is taken into account, but this strength has a downside. One cannot adequately distinguish between perspective and bias. The background that the researcher brings to a scene can be distinctively different from other researchers, and, for that matter, from the perspectives of the participants in the setting. To the extent that the researcher's perspectives differ significantly from the perspectives of the participants—possible because of the generally progressive values and upper middle class status of academics—the understanding of a particular scene may be systematically biased.

2.4 Time

Just as participant observation research is relatively inexpensive, it is also highly labor intensive. This form of research requires that the researcher be present in the observed social scene. One cannot simply fly in and out, but must spend sufficient time so that the full range of activities in which participants engage are noted. Much participant observation depends upon chance—what happens to occur at the moment of observation—and, as a result, a significant investment of time is needed. While there is no definitive rule for the proper length of time necessary for observation, most projects require months, if not years, to complete. This, coupled with a modest requirement for capital equipment support means that, as noted, this methodology is particularly appropriate for younger scholars. This reality can mean that participant observation studies often do not have the depth of theoretical understanding that more likely characterizes the work of senior scholars.

3. The Growth and Development of Participant Observation

Although participant observation methodology has deep roots in ethnographic traditions (including in traveler's tales and missionary tales), participant

observation has its origins in the discipline of sociology at the turn of the twentieth century, particularly with scholars affiliated with the Department of Sociology at the University of Chicago. Notable in this early stage was the participant observation studies of Annie Marion MacLean, a student at Chicago and later professor at Adelphi University. MacLean worked and observed in department stores, sweatshops, and coal-fields, in order to gain an appreciation of conditions in these scenes. By the 1920s participant observation was well established in Chicago, as evidenced in studies by Frances Donovan on the lives of waitresses and Frederic Thrasher's observations of gang life. Although members of the 'Chicago school' of sociology employed numerous methodological techniques, the group was probably best known for their observational research and life stories. By mid-century participant observation had expanded well beyond the bounds of Chicago. Works such as William Foote Whyte's *Street Corner Society* (1943), August Hollingshead's *Elmtown's Youth* (1949), Arthur Vidich and Joseph Bensman's *Small Town in Mass Society* (1958), and Herbert Gans's *The Urban Villagers* (1962), collectively demonstrated that through involvement in a community, the researcher could gain a perspective that was both empirically and theoretically powerful. The fact that many of these research projects covered life in city environments led some to describe this approach as 'urban ethnography'. Another stream of 'participant observation' research was grounded in the study of deviant groups and activities. Researchers in such domains have the dilemma of determining the degree to which participation should bolster their observation. Exemplifying such research are studies of the mentally ill, gang members, and drug dealers, notably the classic works by Erving Goffman *Asylums* (1961), and Elliott Liebow, *Tally's Corner* (1967). These two themes—urban life and social deviance—have been integral to participant observation, and despite reduced interest in the late 1980s and early 1990s, scholars, such as Elijah Anderson, Mitchell Duneier, David Snow, and Carol Stack have returned to these themes, creating a 'new urban ethnography' that focuses on issues of urban poverty and racial injustice.

Not all researchers focus on 'problem domains.' Beginning with the inspiration of the Hawthorne studies, and later the research of Donald Roy and Melville Dalton, increasing attention has been paid to observations of work places. The participant observation of organizational life has developed rapidly, creating an active investigation of organizational domains, both in traditional social science departments and within schools of management. Factories, airlines, restaurants, and high tech engineering firms have all been the focus of research. Yet, all social worlds in which individuals with a common interest meet can be analyzed through participant observation, whether clubs, sports teams, or bars.

4. Comparison with Other Field Methods

It is easy to assert that participant observation is synonymous with qualitative research, and, in reality, the lines are blurred. However, participant observation can be contrasted with several other techniques with which it shares some commonalities. Some scholars engage in 'ethnographic immersion.' In such investigations, the researcher becomes a full member of the group, and, in effect, studies his or her own group. This has the advantage that the researcher comes by his or her 'member's knowledge' naturally, but simultaneously the immersion may diminish the ability to examine the group life from the critical perspective that being marginal sometimes brings. Most participant observation maintains a distinction between the researcher and the full member of the group studied. Typically members are told that they are being observed—an outsider, who, for purposes of the study, may participate actively in the life of the group, even though she or he is not a full member.

A second technique, related to ethnographic immersion, has been labeled 'auto-ethnography,' akin to the methodology of introspectionism of the early years of the twentieth century. In these studies, the researcher mines his or her life experiences, hoping to demonstrate the embodied characteristics of social forces. One such example is Carolyn Ellis's emotional and analytical account of her own reaction to the lengthy dying of her significant other. This writing, while occasionally powerful, insightful, and moving, can be faulted for its reliance on subjective experience. Auto-ethnography might be seen as an extreme instance of total immersion, with nothing outside the researcher's experience; given this, such arguments become difficult for others to evaluate. The author proposes a singular account of her emotions that because it is her account leaves no room for alternative interpretations.

A third, related approach is to collect data by means of in-depth interviews. Most participant observation involves questioning of informants. However, some research relies on this questioning to the exclusion of direct observation. This method has the advantage of permitting the researcher to gain multiple perspectives of the same scene and permits the investigation of domains to which it might be impossible to gain direct access. However, in-depth interviews limit the researcher to the presentations of interested parties. The rhetoric in interviews may be systematically different from the private thoughts of the informant and may also differ from their behavior. Observations provide a check on what one is told for reasons of impression management. As always, triangulation of data provides advantages, curbing the weakness of any one methodology.

Fourth, some researchers de-emphasize participation, and are, in practice, pure observers. Some observers make precise statistical measurements of

public behaviors, but this approach is distinct from participant observation. More relevant are those scholars who examine public behavior, particularly behavior within cities. This distinguished tradition of scholarship includes such researchers as William H. Whyte, Erving Goffman, Lyn Lofland, and, more recently, Carol Brooks Gardner. A close reading of street activity, perhaps parallel to certain forms of animal ethology, permits the recognition of patterns of human activity.

Of course, within participant observation, researchers select various roles or strategies. The key dimension on which roles can be differentiated is the extent to which members are involved within group life. Adler and Adler (1987) divide participant observation methods according to the extent of participation: peripheral membership, active membership, and complete membership. In general, the peripheral member observes as an outsider to the group and its culture, the active member is directly engaged in the life of the group, while making it clear to the group that she or he does not fully belong and is conducting research. In the model of the Adlers, the complete observer essentially engages in ethnographic immersion, sometimes informing the group of the research goals.

5. Strategies of Participant Observation

Unlike many techniques of quantitative research and statistical analysis, there are no firm and fast rules that determine how participant observation research should be conducted. Such a reality has proven frustrating to generations of students. Traditionally a novice learned the skills of participant observation through what amounted to an apprenticeship relation with a senior researcher. However, because of the increasing numbers of field researchers, many social science departments, notably in sociology and anthropology, have instituted field methods courses in which some rudimentary 'rules' and strategies of the method are taught.

5.1 Access

Often the first issue that must be confronted in a research project is the question of access. How does one convince a group that they should open their space to an outsider who may criticize the group? This is surely applicable to groups that are widely perceived as deviant (criminal gangs or politically marginal movements), but it also recognizes that any group, striving to maintain boundaries that differentiate it from others, may engage in some activities that members wish to keep hidden from outsiders and which could be viewed negatively. Participant observers must, within the limits of their ethical standards,

convince the group that they can be trusted. Through this process they set 'the rules of engagement.' Such rules, explicit or implicit, differ for each project. Further, this access involves an ongoing temporal process. One is rarely accepted all at once, but often the group maintains a cautious vigilance until they become satisfied that the researcher can be trusted. The participant observer must be sensitive to this personal equation.

5.2 Socialization

Access is only a first step. Once the researcher gains entrance to a setting he or she must determine what behavior means. In effect, the participant observer must become socialized to the environment with its norms, cultural traditions, and jargon. The ease of this process varies as a consequence of how well acquainted the researcher is with the setting prior to the observation, but unless the researcher begins as a full member, a process of acculturation must typically be mastered. At times, the group may become frustrated by the lack of competence of the observer, but more often this process of learning is valuable in methodological terms, permitting the researcher to ask questions that would be denied to others as being too obvious.

5.3 Developing Relationships

Participant observation is a methodology that depends upon the establishment of relationships. It relies upon sociability. One essential skill is the ability to recruit informants from the field. The most important of these are termed 'key informants,' such as Doc in William Foote Whyte's (1943) classic *Street Corner Society*. These individuals serve both as guides for the participant observer and as a means of vouching for the researcher's legitimacy within the setting, providing an insider's stamp of approval. The researcher who lacks the ability to make connections will have difficulty collecting credible research data.

5.4 Field Notes

The researcher does not only need to observe activity, but must subsequently inscribe that material in 'field notes,' documents that serve as the evidentiary basis of the published report. Considerable discussion has addressed what constitutes appropriate field notes and how these notes should be presented (Van Maanen 1988). These notes provide the 'facts' that are observed, including actions, statements, and the feelings of the observer. Participant observers are enjoined to write as much of what transpires as possible, particularly in the early stages of the research, when one is determining what issues are most salient. This empha-

sizes that participant observation is often an inductive methodology, with the field data revealing the important issues, rather than testing pre-established hypotheses.

5.5 Exit Strategies

Much research simply ends. Once completed, the project closes down. Exiting is not as simple in participant observation because the researcher and informants have developed social ties. Leaving the field involves the termination of a set of powerful relationships, and sometimes produces loneliness or even betrayal. As a result, the process of disengagement often involves a longer period, and some connection with the field setting continues. Researchers are often advised—both for practical and ethical reasons—to share material with their informants, either to gain additional feedback or to permit those informants to use the analysis for their own ends. The linkages that are established during the course of the observation can be a continuing source of strength, both for researchers and for informants.

6. Ethical Concerns

Although all forms of research involving human subjects raise ethical issues, the variety of ethical concerns in participant observation are particularly great because of the degree of interpersonal dynamics involved. Four ethical issues have been central to participant observation research: deception, informed consent, confidentiality, and precision of depiction. Although these do not exhaust potential ethical topics, they raise important concerns.

6.1 Deception

Most participant observers agree that it is both pragmatically and ethically necessary to announce to one's informants that one is conducting research. In part, this is because participant observation depends on the personal relations among individuals, who, for that period of time, are status peers. To claim to be something that one is not—to pretend to be a full member of the group—without revealing one's purpose could undermine the entire enterprise if it becomes discovered. Lies are often difficult to maintain for long periods. Further, deception suggests that one's interests take priority over the interests of another: can we justify such trickery? While research on groups that wish to keep their activities hidden—either deviant groups or, occasionally, elite groups—encourage deceptive practices, such strategies are troublesome.

6.2 Informed Consent

Deception involves the active misleading of others, but how should we view the absence of full disclosure? Do group members have the right to know that they are being investigated? For instance, one can easily join a leisure group without announcing that one is taking notes or planning to publish. Is this proper? As noted, good reasons may exist for announcing one's presence, permitting one's informants to serve, in effect, as research assistants. But should researchers be required to gain the 'informed consent' of their informants; further, how much information is necessary for informed consent, particularly in a research methodology that depends on inductive methods, in which the researcher may truly not be aware of what issues will eventually become central? One's topics depend on what one observes. During the past quarter century, American universities have instituted 'ethics' committees (Human Subjects Committees or Institutional Review Boards), designed to protect the 'rights' of research subjects. Frequently researchers are required to gain some measure of informed consent, but how much information is required remains a matter of debate.

6.3 Confidentiality

One element that most (although not all) researchers agree on is that informants' names and clearly identifying information not be included in any published research report, although some who critically examine elites feel that confidentiality is not essential. In general, researchers typically believe that publishing the names or identifiers of particular informants or settings is neither necessary nor warranted. At times this decision poses a problem in that field notes may describe actions or statements that can be recognized, certainly by others within the scene. As a result, participant observers must choose how much information to alter to preserve confidentiality, even when this shades the full 'facts' of the case.

6.4 Precision of Description

Although it is clearly desirable to present data that is precisely accurate—direct quotations and exact descriptions of behavior—participant observation methodology and the limits of human ability make these values unattainable goals (Fine 1993). In part, we are imperfect in inscribing reality, but in part we may recognize that the details of human activity may actually obscure our crucial analytical points. For instance, false starts, errors, and grammatical infelicities mark the speech of informants, like the speech of researchers themselves. Further, so much behavior is happening at any given moment that the researcher can easily become overloaded with trivial observa-

tions. The ethical balance that must be struck is to do justice to the events that are transpiring, while simultaneously making the account as clear as possible to permit communication with readers.

7. Summary

This brief overview has examined central features of the participant observation methodology. In doing so, it de-emphasized both the strategies of analysis (the extended case study method, grounded theory) used by practitioners and the modes of presentation (realist tales, impressionist tales). No method of data collection can exist without related techniques by which data are analyzed and presented.

Throughout the twentieth century, participant observation proved to be a powerful technique through which researchers understood a diverse set of social worlds in a way that did justice to the complexity of the activities of group members and to their own perspectives and understandings. While this methodology benefits by the triangulation with other styles of research to create adequate theoretical understanding, participant observation provides the basis by which researchers can understand the richness of the social settings that they—and others—inhabit.

Participation: Political

Political participation refers to the activities of the mass public in politics, including, for example, voting

in elections, helping a political campaign, giving money to a candidate or cause, writing or calling officials, petitioning, boycotting, demonstrating, and working with other people on issues. Political participation figures in philosophical discussions of democracy and representative government since ancient times because it provides the means for citizens to communicate their views. Normative interest in the topic remains vigorous (see *Democratic Theory*). This article focuses upon the empirical study of political participation. Scholars look for systematic patterns that explain why some individuals are inactive and why others choose certain activities. The patterns reflect the political context and both reflect and affect the structure of political power.

Participation provides the link from the mass public to the political elite who are presumed—and sometimes shown—to respond (see *Political Representation*).

1. Differing Definitions of Participation

Scholars differ in their definition of political participation. The currently dominant view limits participation to actions that might affect others, as in the following definitions. 'By political participation we mean activity by private citizens designed to influence government decision-making' (Huntington and Nelson 1976, p. 3). 'By *political* participation we refer simply to activity that has the intent or effect of influencing government action—either directly by affecting the making or implementation of public policy or indirectly by influencing the selection of people who make those policies' (Verba et al. 1995, p. 38). The restriction to private citizens is meant to exclude from the concept activity undertaken in their official capacity by those for whom politics and governing are a vocation. A few scholars (cf. Milbrath 1965) include political involvement and activities to support the regime as participation. For these scholars, reading about politics is also political participation, while under the dominant definition it is not (since it does not have direct effects on others).

Another definitional debate in the field concerns the extent to which actions that have the effect of influencing policy without that being the actor's intent also count as political participation. Adopting the more common view, Verba et al. (1995, pp. 38–39) restrict their study to voluntary activity, which they define as follows: 'By voluntary activity we mean participation that is not obligatory—no one is forced to volunteer—and that receives no pay or only token financial compensation.' In contrast, Huntington and Nelson (1976, p. 7) explicitly include not only '*autonomous*' participation but also '*mobilized*' participation, 'defined as' 'activity that is designed by someone other than the actor to influence governmental decision-making'. Under that definition, they would include as a

participant a worker who attends a rally because his boss threatens to demote him otherwise, even if the worker has no intent of affecting government. In practice, it can be difficult empirically to distinguish mobilized from autonomous activity. For answering questions about the impact of participation upon political outcomes, the two are equivalent. The distinction is useful, however, when one focuses on the motives for participation or the impact of participation upon the actor.

2. The Study of Participation

2.1 Participation as Electoral and Hierarchical: Early Studies

The modern empirical study of political participation began developing in tandem with the modern study of electoral behavior using sample survey data. Election outcomes depend not only upon people's preferences but also upon which citizens choose to exercise their preference at the polls. Partially reflecting that link, many of these studies truncated political participation to electoral participation, that is, voter turnout and occasionally some campaign activities (see *Voting: Turnout*). Much empirical work was done in the United States, and much of that was connected to the Michigan Survey Research Center, especially under the leadership of Warren Miller and Philip Converse. These investigators also collaborated with colleagues outside the United States, especially in Europe, producing further studies addressing participation, especially voting. Under the leadership of Stein Rokkan, Scandinavian scholars produced a substantial body of work on participation as part of their more extensive studies of political behavior (see for example Rokkan 1970). These studies painted a clear sociodemographic and psychological picture of voters (and occasionally of participants in campaigns). In contrast to nonparticipants, participants in general had more money and education, were more interested in politics, more partisan, more efficacious, more likely to be men, more involved in organizations, and more rooted in their community. Some, including Rokkan, also paid close attention to the relationship between political behavior, including participation, and the citizen's position in the social cleavage structure.

Milbrath summarized the findings to date in 1965. He included political support as participation as well as electoral activities beyond voting. He promoted the influential organizing idea that participation lay on a hierarchical scale—there was a ladder of activities, with the easiest at the bottom and the most difficult at the top. 'Persons who engage in the topmost behaviors are very likely to perform those lower in rank also' (Milbrath 1965, pp. 17–18). Given the emphasis on electoral activities and given the frame created by the

ladder concept, levels of participation in the United States were perceived as low.

2.2 Large-scale Cross-national Studies

Interest in democratic stability prompted cross-national projects that took political participation as an important variable. For Harry Eckstein, participation provided the link upwards from subordinates to superordinates (Eckstein and Gurr 1975, pp. 60–7). For Almond and Verba in *The Civic Culture* (1963), the participatory behavior of citizens in a country was one important component in characterizing their political culture, but they were just as interested in attitudes and beliefs about hypothetical behavior as in activity. Nonetheless, the data, collected in 1959 and 1960 in five countries (the United States, Mexico, Italy, West Germany, and Great Britain) provided the first major database used for cross-national comparisons of political participation, especially beyond voting turnout. Some of these analyses contributed the important conclusions that persons involved in organizations participate more in politics and that societies with denser organizational structures exhibit higher levels of participation.

Within the decade (1966 to 1971) Verba was in the field again, with an international team of collaborators, studying political activity. Surveys were completed in the United States, Japan, Austria, the Netherlands, India, Nigeria, and the former Yugoslavia. Some of the first products of this research (e.g., Verba and Nie 1972) overturned the conception of participation as a hierarchy of electoral activities. Instead, participation was expanded to include non-electoral activities and reconceptualized as modes of activity in any one or more of which individuals might specialize. Although often these are positively correlated, meaning that a participant in one is more likely to take part in others than a randomly selected person, many people nonetheless partake in one or some to the exclusion of other forms of participation. In particular, substantial numbers of people who avoided electoral politics did engage in nonpartisan participation, such as involvement with community groups.

As reported in Verba and Nie (1972) and Verba et al. (1978), as well as other publications from the project, wealth and education were reaffirmed as important predictors of participation. But the main theoretical point is that the strength of that relationship varies across societies as a function of the strength of other, 'group,' resources. Where these are strong, such as in countries with strong political cleavages tied to ascriptive characteristics, or with sociological or occupational segments with strong political leadership, the relationship of socioeconomic status (SES) to participation was relatively weak. Certain well-off segments of the population were 'inhibited' from

participation while other, possibly disadvantaged, segments were 'mobilized,' thereby together attenuating the relationship between SES and participation. While others had noted similar phenomena, the finding now had wide cross-national grounding.

The Verba and coworkers' studies deliberately ignored political protest, that is, participation in activities outside accepted conventional norms, including some that are illegal. This omission seemed unfortunate by the 1970s in light of the frequency of real-world protest. Out of the study of revolution and political violence (see *Revolution*) came renewed interest in relative deprivation. But many protest activities are not violent (see *Political Protest and Civil Disobedience*).

A group of European and American scholars launched the Political Action project, a cross-national study focused on protest. They conducted surveys in the United States, West Germany, the Netherlands, Great Britain, and Austria in 1973 to 1974, in Italy, Switzerland, and Finland two years later, and a second wave in the first three countries in 1979 to 1980. The results appeared in *Political Action* (Barnes et al. 1979), *Continuities in Political Action* (Jennings et al. 1989) and other publications. One objective of this research was to understand the relationship between protest and conventional participation. The Political Action project clearly showed that enough persons who participated in conventional politics were adding protest to their 'action repertory' to conclude that conventional and protest participation were complements rather than substitutes. The Political Action studies differed from their predecessors in showing that variations in values predict both who will be active and the form of their activity. Specifically, persons with postmaterialist values are more active and more likely to protest than are materialists. Interpretation of the results is hampered slightly by the inclusion of respondents' hypothetical willingness to protest in some of the measures of protest activity.

Other scholars investigated the effect of political institutions on participation. In particular, they showed that cross-national variations in voter turnout rates reflect differences in electoral systems, party competitiveness, registration systems, government structure, and requirements to vote (see *Voting: Compulsory*).

Attention to participation in organizations shades into studies of social movements. Where a political scientist sees a participant in a voluntary organization addressing a specific problem (and thus somehow engaged in the communal mode of participation), a sociologist sees someone active in a social movement. The latter have produced another extensive, related literature.

Approaches and/or theories from these cross-national projects have been influential in many country-specific studies of participation. These studies have contributed much that is new, but their con-

clusions have also tended to support the theories developed in the large projects.

2.3 *Mobilization as a Predictor of Participation, Not a Type, and the Civic Voluntarism Model (CVM)*

The next major theoretical development in the study of participation involved incorporation of the recognition that people are more likely to participate when they are asked to do so (i.e., when they are 'recruited' or 'mobilized') and, moreover, that mobilization follows systematic patterns. Rosenstone and Hansen (1993) developed this idea in their study of participation in the United States from 1956 to 1990, claiming that a decline in mobilization over that period accounts in large part for the observed decline in participation.

Verba et al. (1995) use the related concept of 'recruitment' cross-sectionally in their study of political participation in the United States based on a 1989–1990 survey. It is the third component of the CVM; the first two are 'resources' and 'engagement.' They argue that higher levels of any of these factors lead to greater participation—people participate in politics because they can, because they want to, and because someone asks.

'Resources' are most readily measured by income and education, but these serve as proxies for more fundamental measures. The most interesting components of resources are the 'civic skills,' operationalized by Verba et al. (1995) as writing a letter, making a speech, and attending or planning a meeting where decisions are made in one or more nonpolitical settings, such as on the job, at church, or in a voluntary association. Civic skills turn out to explain the long-observed association between organization membership and participation. 'Engagement' includes interest, efficacy, political information, and partisan attachment, and also specific issue or ideological concerns. Note the connection between this part of the model and the finding that postmaterialists are more participatory. 'Recruitment' includes both requests from individuals and those from persons in authority (e.g., on the job, at church, or in an organization). This latter route provides one path by which group resources operate.

People with greater wealth and education in general have more resources, are more engaged, and are more likely to be recruited, so overall the relationship between socioeconomic status and participation is positive. The CVM model provides a fuller understanding however of why the relationship holds. Moreover, were it applied cross-nationally, it would point to components that need measuring. For example, churches play a role in the United States not likely to be replicated elsewhere.

Cost and benefit analyses inspired by rational actor models influence much contemporary work on participation, including that of Rosenstone and Hansen

(1993) and Verba et al. (1995) (see *Rational Choice in Politics*).

Many of the factors that lead to high levels of political participation are associated with high levels of social capital (see *Social Capital*) notably including substantial organizational involvement. Since social capital is also measured with political participation, the relationship among the concepts and the phenomena need more attention.

3. Conceptual Issues in Research on Political Participation

3.1 Participation Outside Advanced Democratic Countries

Most of the research discussed above has focused on economically-advanced democratic countries, with the occasional addition of other research sites. The restriction to democratic countries reflects the particular role of political participation in a democracy. Participation provides the means by which people control their government, most decisively so in elections which determine who rules. The unique power of the vote to change rulers provides the force for most of the other modes of participation. Campaigning, expressions of opinion, community organizing, and other actions command attention in part because ultimately the opposition can win an election.

In an authoritarian regime, the electoral connection no longer exists. Nonetheless, there is still political participation. Although the people no longer select the rulers, the rulers still need to keep the population reasonably satisfied to forestall revolt, and, to do so, they need information on the people's preferences, and they need to respond to discontent. Several very interesting studies have examined participation in authoritarian regimes, such as Friedgut's study of the USSR (1979) and the work by Shi (1997) on China.

In economically less-developed countries, one frequently finds that government institutions are also less well developed, that the associational networks are weak, or that loyalties to local groups outweigh those to governmental institutions. In these circumstances, much political participation may consist of informal involvement in the local arena or in traditional institutions (see, for example, Dietz 1998).

Issues of cross-national and cross-cultural comparability loom large in all studies of participation, but they are especially salient for research in non-democratic or less-advanced countries. One must rethink what counts as 'political' in these contexts in light of the institutional situation. For example, some of these studies led to the suggestion that participation includes activity directed towards altering the implementation of policy, rather than just its formulation, or that bribery is an important mode. Certain

actions that are nominally the same can serve very different functions in differing contexts. For example, 'voting' may just show regime support in one country but select a government in another. The independent variables of importance also vary. For example, because of the particular circumstances in China, 'education' does not usefully measure resources there (Shi 1997, pp. 145-8). In many countries, other institutions are likely to play the role of churches in the United States as a source of civic skills.

Matters become more complex when an authoritarian regime democratizes. Many current studies examine participation in Eastern Europe and the republics of the former Soviet Union. With the abrupt changes in regime, the process of political socialization (see *Socialization: Political*) will probably also change, providing good conditions in which to observe the effect of political attitudes on participation.

3.2 Leadership

If people participate more when they have resources, are engaged, and are recruited, then elite action can significantly alter the level of participation by affecting engagement and recruitment. Political leaders provide resources to make participation easier (such as a babysitter, a ride to the polls, or information on what to support). Leaders contact people, directly or through proxies, asking them for action. Leaders can increase engagement by framing the public debate in a way that increases the stakes of political competition by communicating this message to their listeners.

The contemporary mass media play a role very similar to leaders. They frame issues and strongly affect (at times, negatively) engagement and recruitment. However, their motivations differ from those of leaders as they seek attention rather than support, and their actions are not targeted.

The political world contains many persons vying for power, each of whom needs large numbers of supporters to achieve power. Only some are successful in recruiting others and, as noted above, theory has not yet explained the circumstances of success. But political participation will increase when many are active and successful, and it will be higher than otherwise expected for persons who are targets of their efforts.

Parties: Litigants and Claimants

This article focuses on parties who are subject to legal proceeding in a nonprofessional capacity. Excluded are lawyers, judges, and other officials who make their living from legal work; also excluded are the individuals who serve as witnesses and jury members in trials. The focus is on actors who are the *subject* of legal decisions. They include litigants, claimants, and those subject to investigation and scrutiny by law enforcers in both criminal and administrative capacities.

It is important at the onset to differentiate between those who initiate legal proceedings and defendants. Plaintiffs in civil courts and complainants in criminal courts exercise volition in choosing to take disputes to court. While defendants in criminal and civil court proceedings may indirectly exercise volition, in the sense that the legal proceedings may be a consequence of their own prior decisions, the choice to be involved in the legal proceeding itself is typically not something they would choose on their own.

Disputes and allegations of illegal behavior that end in court are merely the tip of the iceberg (Felstiner et al. 1980–81). On the civil side, people may formally or informally negotiate a settlement ‘in the shadow of law’, or may ‘lump’ an unresolved dispute due to high costs of proceeding, inability to find an advocate who will take the case, or fear of retaliation for making legal claims. In many places, criminal cases are resolved by plea bargains instead of a formal trial. Complainants may also have their cases turned away by gatekeepers as not being sufficiently ‘legal’ to warrant court attention (Yngvesson 1993, Merry 1990).

1. Dimensions of Difference in Parties

The research literature focuses on (a) the distinction between individuals and organizations, and (b) demographic differences related to social power—primarily gender, race, and class. Both lines of research attempt to account for differences in the experiences of various types of parties with legal systems, but in somewhat different ways.

Comparisons of individuals and organizations have been made in studies testing Marc Galanter’s theory of why ‘haves’—parties with greater resources—may have a greater advantage in legal settings (Galanter 1974). Most empirical tests of the theory have examined success rates for different classifications of organizations compared to individuals and each other, using appellate court cases in which there is a written record. In addition, white-collar crime research has also emphasized differential treatment of organizations and individuals, and poses additional explanations for why organizations may experience more advantageous treatment than individuals when they violate the law.

Studies of gender, race, and ethnicity tend to focus more on case processing, and to examine variations among different categories of individuals in far greater detail, with minimal attention to variations among organizations. A variety of methodologies have been employed, including observational studies, analysis of legal cases, and quantitative survey studies. Some studies focus on variations in resources and skills that affect an individual’s chances of negotiating successfully through legal proceedings, while others focus on the social categories and standards used by legal decision-makers in making decisions on how to proceed with cases.

2. Comparisons of Individuals and Organizations

Galanter’s classic 1974 article ‘Why the “haves” come out ahead’ argues that organizations are more likely, compared to individuals, to have structural advantages that increase the likelihood of winning in court. In addition to their greater financial resources and

ability to hire legal talent, large organizations are more likely to be 'repeat players' who are better able to mobilize legally and to use law to meet strategic goals (Galanter 1974). A number of studies of state and federal appellate court decisions have found support for Galanter's argument (Songer et al. 1999). The most consistent finding is that government organizations, particularly federal and state governments, experience a substantial advantage over both business and individuals, while business organizations appear to have a modest advantage over individuals. Studies that distinguish between larger business corporations and smaller business organizations generally find a stronger advantage for big business (Farole 1999, Songer et al. 1999).

Much of the appellate court research has been conducted in the United States, but similar patterns have also been found for other countries governed by the English common law tradition. Moreover, Songer et al. (1999) found considerable stability over time of the basic pattern of results for the US Court of Appeals, suggesting some generality to the pattern of greater organizational success in appellate courts.

A study of Philippine Supreme Court decisions, however, found strikingly different results, with individuals experiencing greater success in winning cases than organizations (Haynie 1994). Haynie speculates the legitimacy of high courts in developing countries may be more precarious. This may lead courts to make more decisions with redistributive effects in a bid to enhance their legitimacy by establishing their independence from other powerful actors in society.

Research on lower courts points to mixed evidence regarding the thesis that organizations are advantaged over individuals. Anthropological studies of the lower courts suggest that organizations face fewer difficulties than individuals in getting their complaints against others into court. Yngvesson (1993) found that the majority of complaints brought by individuals were characterized as 'garbage' cases by court clerks, who often expended considerable effort to keep them out of court (see also Merry 1990). In contrast, complaints filed by police officers—representatives of a local governmental agency—were routinely admitted with minimal review as to their appropriateness for legal action. Similarly, motor vehicle complaints, code violations, and welfare fraud cases filed by government agencies, as well as debt collection cases filed by local businesses, were given a higher priority.

No doubt one of the reasons why complaints filed by the police, other government agencies, and businesses were more readily accepted and processed by the lower courts is that they are more likely to be explicitly linked to legal provisions and couched in the language of law and legal doctrine. This is in part due to the focus of such cases on disputes about money and property, while complaints brought by individuals tend to involve interpersonal disputes and problems with relationships. In addition to the more explicitly

'legal' character of property disputes, the greater training and proficiency of organizational representatives in formulating their complaints in legal terms may also assist getting borderline cases into court. As one police officer stated, while discussing a complaint he filed of 'deliberate and malicious' damage to a tree. *If you really want to, you can find a law to do what you want to do* (Yngvesson 1993, p. 21; emphasis in original).

Organizational studies abound with examples of the strategic use of the law to achieve organizational goals. Examples in the business sector include innovative interpretations of tax laws in tax avoidance schemes (McBarnet 1991) and the strategic use of bankruptcy law (Delaney 1992). In the government sector, prosecutors in the USA have creatively used the RICO (Racketeer-Influenced and Corrupt Organizations) law to expand prosecutions beyond the original target of organized crime to include white-collar crimes such as commercial and financial fraud, tax evasion, embezzlement, and bribery (Friedrichs 1996).

While the extension of RICO laws to white-collar offenses offers an example of legal innovation that increases the advantage of large government organizations over individuals and business organizations, the research literature on white-collar crime finds that, as suspects and defendants in criminal proceedings, organizations are advantaged over individuals. As Sutherland (1983) noted, illegal behaviors by organizations are typically handled by regulatory agencies instead of criminal law enforcement agencies. Sanctions by regulatory agencies are relatively mild, typically involving fines, cease and desist orders, and other civil sanctions. While regulatory agencies may seek criminal sanctions, the criminal prosecution of organizations remains relatively rare.

The allocation of cases of organizational misconduct to civil courts and administrative enforcement, rather than criminal courts, cannot be attributed to a lesser seriousness of organizational misconduct generally. Cost comparisons typically find that illegal behaviors by organizations tend to be more deadly and expensive in the aggregate than crimes committed by individuals (Poveda 1994). Survey research generally finds that the public considers corporate crimes that result in loss of life as serious in nature (Friedrichs 1996). Some authors have also argued that greater alienation and cynicism by the public against public institutions generally is an additional cost of organizational crime (Maier and Short 1995).

Various explanations exist for why 'street crimes,' primarily committed by lower-class individuals, are relegated to the criminal courts, while offenses of organizations are handled primarily by civil courts and administrative enforcement actions. Legal conflict theorists argue that those who have power and money are better able to influence legislators to exclude their behavior from criminal statutes (Green 1997). Even

when laws define misconduct by organizations as criminal, practical difficulties to securing criminal convictions include the diffusion of responsibility within organizations, and the greater complexity and cost of amassing evidence for organizational crimes (Friedrichs 1996).

Moreover, contemporary theories of organizational misconduct point to the influence of organizational culture and processes or organizational decision-making as causes of misconduct that do not conform easily to models of individual choice such as underlie much of the criminal law (Ermann and Rabe 1997). As Vaughan notes in her study of the *Challenger* disaster, 'repetition, seemingly small choices, and the banality of daily decisions in organizational life—indeed, in most social life—can camouflage from the participants a cumulative directionality that too often is discernible only in hindsight' (Vaughan 1996).

Finally, the pragmatics of securing cooperation from organizations to prevent future harms may be a key factor in the allocation of law enforcement activities related to organizational misconduct to regulatory agencies. While US regulatory agencies have historically been more likely to use adversarial, deterrence-oriented tactics such as the imposition of fines and penalties, regulatory agencies in most countries typically focus their energies on using educational and persuasive techniques to secure compliance (Braithwaite 1985).

The primary rationale for cooperative law enforcement strategies is that, while compliance with law for individuals often means refraining from committing illegal acts, compliance for organizations typically involves perspective behaviors, such as buying new equipment, training employees, and undertaking new routines and processes that are both expensive and time-consuming. Utilizing adversarial tactics may be counterproductive if they result in organized resistance by powerful actors (Bardach and Kagan 1982). Braithwaite (1984) frankly notes that a consequence of cooperative enforcement techniques is the introduction of distributive inequities, but argues that the payoff in increased effectiveness in saving lives and reducing human misery is worth the cost.

Counterbalancing the advantages organizations have in avoiding criminal proceedings for instances of illegal behavior, research on the civil courts typically finds that, when cases go to trial and the plaintiffs win, civil court verdicts are typically harsher for organizations than for individuals (Chin and Peterson 1985, Maccoun 1996). The 'deep pockets' hypothesis suggests that organizations are both more likely to be sued and to have higher damages assessed because they usually have more assets than individuals. While 'deep pockets' may explain decisions by both potential plaintiffs and attorneys to pursue cases, jury simulation studies have found little evidence that greater wealth explains the differential size of damage awards. Instead, it appears that juries apply different standards

to organizations than individuals (see Maccoun 1996). However, the greater harshness of civil damage awards against organizations should be placed in context, in that few lawsuits go to trial.

3. Demographic Differences Related to Social Power

Other articles in this encyclopedia discuss race, class, gender, and the law in greater detail than is possible here. The purpose of this article section is to contrast apparent commonalities in what legal parties want from legal decision-makers with the difficulties they may experience in obtaining what they want due to barriers arising from their position in society.

Research on procedural justice suggests a high degree of commonality in what people want from legal proceedings (Lind and Tyler 1988, Tyler 1988). Studies conducted in different countries and in a variety of legal settings have consistently found that perceptions of fair process affect satisfaction with legal experiences as much or more than objective outcomes and perceptions of distributive justice. Moreover, procedural justice perceptions are generalized beyond the specific experience to affect the legitimacy of other legal and political authorities (Lind and Tyler 1988) and also expectations of fair treatment in other legal settings (Stalans 1994).

According to the group-value model of procedural justice, encounters with legal authorities convey profoundly symbolic messages to individuals about their social standing (Lind and Tyler 1988, Tyler and Lind 1992). The concept of standing emphasizes basic concerns individuals have about their membership and inclusion in social groups, about whether they are valued members of the community. Tyler (1988, 1994) argues that a substantial consensus exists on how people define procedural justice, and suggests that fair process is a means by which multicultural societies can maintain their legitimacy amid the diverse goals and interests of different groups within society. Results from other studies, however, caution that procedural justice may be a less important concern than outcomes for people who do not have a sense of identification with the larger collectivity (Huo et al. 1996).

Despite the emphasis of the group-value model of procedural justice on social standing and intergroup relations, surprisingly little procedural justice research explicitly addresses issues of social stratification. Yet many of the most pressing and controversial issues in law and society research involve the ways in which external social structures of power and domination are reproduced in legal settings during the enactment of legal procedures.

Anthropological research indicates that social stratification is intertwined with relational concerns and definitions of 'legal' issues in ways that systematically

privilege some groups over others in actual legal proceedings. To begin, the types of disputes that are often of central concern to women and lower-income individuals involve troubled relationships, including domestic violence. Yngvesson (1993) notes that clerks in New England courts were reluctant to bring cases involving relationship problems before judges. Even divorce lawyers who make their living from the dissolution of troubled relationships tend to be unresponsive and aloof to clients' tales of relational woes (Sarat and Felstiner 1995).

Merry (1990) notes that cases involving relational issues are more likely to be diverted from court into mediation—and that mediation itself and the court employees who manage mediation have a devalued social status in the court system. While mediation explicitly focuses on relationship issues, the application of rules of discourse that discourage conflict during the process of mediation may serve to systematically disadvantage women, compared to more adversarial court proceedings that focus on advocating and protecting legal rights (Conley and O'Barr 1998).

Discomfort with handling troubled relationships is not confined to Western legal systems. Griffiths (1997) reports that, in Botswana, a common ruling by *kgotla* in marital disputes is simply to order the parties to go home and 'live together in harmony and peace.' In Kenya, Swahili women who tell stories of domestic conflict and discord in Islamic Kadi courts violate social norms against revealing family secrets in public (Hirsch 1998). While some African courts encourage the airing of relationship issues, detailed analyses reveal the systematic shaming of women during the process of talk about relationships (Conley and O'Barr 1998).

The devaluation of relationship talk surfaces in Conley and O'Barr's study of US litigants in small claims court. Conley and O'Barr described two distinct types of narrative structures used by litigants. Rule-oriented accounts are ordered sequentially, describing the unfolding of events in a linear fashion while noting violations of specific rules, duties, and obligations by the other party. They articulate cause and effect and assess responsibility. Relational accounts, on the other hand, focus more on social position and general rules of social conduct. They are more likely to be full of details about the life of the speaker and the history of his/her relationship with the other party, including details that are not relevant to the legal issue at hand.

As Conley and O'Barr (1998) note, rule-oriented accounts conform to the logic of law in Western societies. Legal decision-makers readily understand rule-oriented accounts, while they have more difficulty processing relational accounts. It takes more work for judges and lawyers to translate the jumbled and rambling accounts in relational narratives into the rule-oriented framework of law. Many do not make the effort, to the disadvantage of individuals who

employ relational accounts. This gives an advantage to repeat players, to those who can afford to hire legal counsel, and to better-educated, more articulate parties who bring to court greater skills in couching their narratives in forms readily comprehensible to legal decision-makers.

Conley and O'Barr also describe stylistic features of speech that can serve to reproduce structures of social domination (Conley and O'Barr 1998, Ainsworth 1993). Conley and O'Barr note that women and men of lower social status in society are more likely to evidence styles of speech that project deference and uncertainty, thereby undermining their own credibility. 'Powerless' speech includes the use of hedge words, polite forms, tag questions, exaggerated imprecision about quantities, and a rising intonation at the end of declarative statements. Although Lakoff (1975) first identified these speech styles as gendered features of language, studies in legal settings have found that some men also use these forms of speech, to their detriment (Conley and O'Barr 1998, see also Ainsworth 1993).

While dominant social orders tend to reproduce themselves in legal settings, the process is by no means immutable and unchanging (Griffiths 1997, Hirsch 1998). As Conley and O'Barr (1998) note, many individuals of subordinate social status are capable of adopting a rule-oriented discourse strategy and modifying their speech styles. In addition, the existence of a 'chivalry bias' favoring women in criminal cases (Anderson 1976) and the harsher sentences given to high-prestige individuals convicted of white-collar crimes (Weisbrud et al. 1991) highlight that the general social order is not simply reproduced in legal settings, but can be transformed in ways that create reversals of social fortune.

At the same time, it is important to note that some patterns of domination and unequal treatment are more deeply engrained in the fabric of legal interactions and less amenable to modification or manipulation (e.g., Matoesian 1993, 1995). Studies of legal case processing in particular illuminate seemingly ubiquitous processes of social categorization of parties by legal decision-makers according to race, class, and gender in the course of identifying suspects, managing caseloads, evaluating credibility, and making decisions about how hard to work on cases (e.g., Waegel 1981, Frohmann 1997). While social categorization often works to further organizational goals and to increase the speed and efficiency of legal decision-making, it does so at the cost of procedural and distributive inequities that arise when individuals are judged through the prism of presumed group characteristics.

Parties/Movements: Extreme Right

Political parties and movements that current conventional labeling by political scientists and other informed analysts would regard as of the extreme right have emerged in many countries and on many occasions, since at least the early nineteenth century. The label, as currently employed, is necessarily an encompassing one because it is applied incontrovertibly to numerous parties/movements that nonetheless differ from each other in other ways, and also, more contestably, to certain political formations onto which not every recognized specialist is willing to confer that designation. Some analysts have preferred descriptions such as 'neo-populist' or 'right-populist' for movements not universally classified as 'extreme right.'

1. The Term 'Extreme Right'

The term 'extreme right' can be shown to have been used in a political sense, but not with quite its contemporary meaning and connotations, since the mid-nineteenth century and before. However, the term and its cognates are surprisingly recent arrivals in political science's standard vocabulary, having been regularly employed in the discipline only since the late 1950s. Lipset, for example, used the term very occasionally in his *Political Man* (1959/1963), it became conventional usage among European (except German) commentators during the 1960s, and it achieved final recognition in American political science with Lipset and Raab's *The Politics of Unreason* (1970/1971). One reason for the slowness with which the actual term came to be adopted in the USA was the popularity of the alternative, and still used, 'radical right' in order to describe political phenomena that most, but not all, present analysts would now call 'extreme right.' Lipset had also been responsible for the introduction of the term 'radical right' into US political science, and so for its popularity during much of the following decade. It was perhaps taken from the usage in German of *rechtsradikal*. This neologism, although also postwar, can be traced back to its introduction into German in the early 1950s, probably influenced by the fact that Germany's most significant extreme right party was then the later proscribed *Sozialistische Reichspartei* (SRP). This designation, though sometimes also *extrem rechtsradikal*, was widely used by German authors in the 1960s and 1970s, and has only relatively recently been superseded among political scientists by *rechtsextrem/rechtsextremistisch*. The distinction was also a bureaucratically important one in Germany, since a purported and casuistical distinction between *rechtsradikal* and *rechtsextrem* was the basis on which the German Office for the Protection of the Constitution justified varying monitoring and control strat-

egies toward different right-wing formations. By the 1990s extreme right activities in Germany made this distinction increasingly dubious and inoperable, and the latter term now in practice subsumes the former one.

2. A Definition of 'Extreme Right'

A definition of extreme right parties/movements has necessarily to be extensive and complex, for it must be appropriate for such movements as diverse in time and location as the American Anti-Masonic Movement of the 1820s; the Know-Nothing Movement of the 1850s; the French Boulangist Movement of the 1880s; inter-war fascism in Italy and other European countries; Nazism in Germany; McCarthyism in 1950s USA; Poujadism in 1950s France; George Wallace's 1968 American Independent Party (AIP); more recent European examples such as the French *Front National* (FN) and the German *Die Republikaner* (REPs); Latin American paramilitaries in countries such as Nicaragua and Colombia; Vladimir Zhirinovskiy's Liberal Democratic Party in Russia; and even purportedly more mainstream political parties of the present such as Austria's *Freiheitliche Partei Österreichs* (FPÖ) and Switzerland's *Schweizerische Volkspartei* (SVP). The contemporary American militias are usually regarded as extreme-right, but they are idiosyncratic examples, their most obvious European analogue perhaps being the militant neo-Nazi defense groups of Germany and some Scandinavian countries. Although not all analysts would agree on the 'extreme right' designation for every one of these, each has nonetheless attracted many such attributions from historians, political scientists, or informed journalist observers. Commentators from some countries (such as France and The Netherlands) have been more ready than those elsewhere unwaveringly and without collateral justification to label the contemporary examples as 'extreme right.' An inclusive definition of the extreme right has to be based on ideological features such as those below and, although each would not necessarily apply with equal emphasis and significance to all extreme right parties/movements, all political scientists using this concept would understand that many or most would, at leadership or mass-support level, characterize a political phenomenon so designated:

- selective inclusion, especially within the nation and often based on imposed assumptions about ethnic or religious similarity (which may take the form of aggressive nationalism or ethnocentrism);

- selective exclusion, directed against foreigners and/or indigenous or immigrant ethnic minorities, but also against social minorities such as homosexuals, travelers (gypsies), or in the past even the Masons;

- racism, based on biological perspectives about supposed inferiority or on the fabrication of ethnic and cultural boundaries;

anti-Semitism, which may be both specific and directed at contemporary targets, but which may in some cases involve denying, or mitigating the scale of, the Holocaust and glorifying the deeds of the Third Reich;

a preference for authoritarian initiatives by a strong state;

the cult of a leader figure;

a preference for a hierarchical social order;

antisystemic and antipluralist political perspectives;

overt hostility to political opponents, often associated with the use, encouragement, or tolerance of violence;

low tolerance of social change; and

nostalgia for the past.

2.1 Extreme Right Phenomena in the Twentieth Century

It is useful to give a very general, if crude, periodization for extreme right phenomena of the twentieth century, although in each of these periods there was nonetheless a considerable variety of such parties/movements:

1920–45. The era of ‘classic’ anti-Semitic Nazism and fascism.

1945–70. The era of the ‘old wave’ extreme right, often comprising anti-Semitic neo-Nazi/neofascist movements with a yearning for the ‘classic’ era (e.g., the SRP or Italy’s *Movimento Sociale Italiano*, MSI) and nostalgic anticommunist movements (e.g., McCarthyism).

1975–present. The era of the ‘new wave’ extreme right, appealing particularly on a basis of xenophobia and racism against ethnic minority immigrant groups and asylum seekers.

This periodization is not perfect, particularly because of anomalies among the US cases: the AIP, for example, anticipated the issues of the ‘new wave’ extreme right. However, it is a useful heuristic device for discussing theoretical approaches to the analysis of these movements.

3. Theoretical Approaches to the Extreme Right

Fashions in political science towards the analysis of the support of extreme right parties/movements have not been constant. While it is important not to exaggerate these changes, it is true that research in the 1950s and into the 1970s, conducted on the vote for Nazism (the *Nationalsozialistische Deutsche Arbeiterpartei*, NSDAP) and on ‘old wave’ postwar movements, was especially concerned with answering questions about the partisan origins and the social base of these examples of extreme right support. The lack of any individual-level data on voters for the NSDAP led to the use of different combinations of aggregate data in a substantial body of research about

Nazism’s partisan origins and social base. The most recent and comprehensive research in this tradition has argued the case for considerable social variety in the NSDAP’s later support. Postwar movements for whose support there existed survey data were frequently analyzed in the first instance in terms of the social categories to which they particularly appealed. Ideological and attitudinal dispositions towards the extreme right were not ignored, of course (especially not by research drawing on perspectives in *The Authoritarian Personality*, Adorno et al. 1950), but they were not always treated as the principal explicandum; indeed, many authors (e.g., some of those writing about McCarthyism in *The Radical Right*, Bell 1963/1964) simply imputed motive. Researchers working on movements that have emerged in the ‘new wave’ era have been more inclined to recognize that most extreme right movements draw from a variety of social sources and have given greater attention to the attitudinal, psychological, and contextual bases of such support. The disproportionate support for many ‘new wave’ extreme right movements among the self-employed and among younger voters from manual-worker backgrounds (especially males) has been noted (e.g., in the cases of the FPÖ, the FN, and the German *Deutsche Volksunion*, DVU), but it has not been a central plank to theorizing about these movements.

In giving an overview of the theoretical perspectives towards extreme right parties/movements, it is essential to distinguish between the pre-World War II and postwar cases. Many of the interbellum movements played major political roles, especially so, of course, in the cases of Italy and Germany. Even in countries where such movements did not achieve power, they often had substantial impact upon national politics during the 1930s (as in France or The Netherlands). On the other hand, in the postwar period extreme right parties/movements, though not without some important effects upon the content of political agendas, have not usually achieved actual governmental office—significant exceptions being Italy briefly in 1959 and during the mid-1990s, Austria in 2000, as well as the problematic cases of Spain till 1975, and of contemporary Switzerland in the light of the recent metamorphosis of the SVP towards the extreme right.

Most contemporary theoretical analyses of the interbellum extreme right focused on German Nazism and Italian fascism. Some influential perspectives came from self-avowed Marxists and, though incorporating views about the social base of these movements, attributed to them a particular role in the balance of class forces. Perhaps the more subtle of these Marxist perspectives were those by Gramsci, who used a concept of Caesarism, and by Trotsky and Thalheimer, who drew Bonapartist analogies and regarded fascism as a resort by capitalists to perpetuate their interests in a situation of class stalemate between the proletariat and capital. Postwar Marxists have

sometimes resurrected such perspectives in looking at Italian fascism and Nazism and have even sought to apply them to postwar movements, but, to most analysts, these approaches are no longer relevant. Instead, the great majority of political scientists writing on the 'old and new wave' extreme right have sought, albeit in varying ways, to focus on the social situations that may produce extreme right sympathy and behavior.

A widespread feature of numerous theories of both the 'old and new wave' extreme right is to see them as supported by those who in some way have suffered, or see themselves to have suffered, from social change. This theorizing may take the form of predicating status loss (e.g., Hofstadter and Lipset on McCarthyism), or disorientation as a result of social strain (e.g., Parsons), or a reaction against the growth of postmaterialist values (e.g., Ignazi), material loss due to processes of modernization or globalization (e.g., Heitmeyer). Theories with a social-psychological basis, as by those who have applied perspectives derived from *The Authoritarian Personality* and the Frankfurt School to 'old and new wave' movements, also assume a resistance to, and intolerance of, certain types of social change. 'New wave' extreme right movements since the 1970s, because in many cases they have made racism and xenophobia the principal basis of their appeal, have particularly attracted theorizing seeking to explain the presence of such attitudes among individual voters and certain groups of voters.

4. *The Tendency of Extreme Right Parties to Schism*

Extreme right parties/movements frequently exhibit distinctive organizational characteristics in comparison with mainstream political parties. The former have a particular tendency to splits, and contain strong schismogenetic features. This is sometimes because of personal animosities between leaders, who are often psychologically disposed to be authoritarian and are intolerant both of different perspectives and also of rivals. Because of the variety of ideological appeals offered by extreme right parties, their leaderships and supporters often have a mixture of social origins and this too can lead to divisive differences over minutiae of ideology (a characteristic shared with extreme left movements). Extreme right parties, particularly those in the postwar 'new wave' period, have exhibited a remarkable tendency to fracture. In France, Germany, Great Britain, The Netherlands, and Switzerland, to name only some examples, the indigenous extreme right has had a history of division and internal dissension. Indeed, many of the apparent electoral successes in the 1980s and 1990s by extreme right parties foundered on the organizational collapse of the elected legislative grouping, something that has been a

particular feature of the German extreme right parties, the REPs and the DVU.

5. *The Future for Extreme Right Parties/Movements*

It would be scientifically insupportable to suggest that such parties/movements will wither away. A troubled world is likely to provide just too many dynamics to underpin their emergence, especially in certain Third World contexts. In the liberal democracies, however, despite some successes in obtaining municipal control (as the FN has had since 1995) and breakthroughs by parties such as the FPÖ and the SVP (both of which emerged from mainstream political formations), there are few indications in most countries that, on a national level, extreme right parties will emerge on any scale from a political exclusion zone. Support even for the most successful examples has in most cases reached a zenith and elevated levels of one-time support frequently erode. These parties depend on a pariah status for attracting the votes of the politically alienated, and sometimes, as in France, where a party faction has wanted to seek accommodations with mainstream politics, the result has been a damaging split to the greater disadvantage of the faction arguing for such a rapprochement.

Partner Selection across Culture, Psychology of

Although family structures, forms, and functions vary across cultures, marriage is a central universal phenomenon in the lives of most people. Selection of a partner is a key facet of marriage, and its mechanisms vary in consonance with the social psychological construction of the concept and meaning of marriage in a given culture. Every culture has rules or normative frameworks governing the orientation towards partner search and selection.

Interestingly, a range of changes is evident in partner selection within and across cultures, some of which are a consequence of the shifts in the macro contextual conditions, such as socioeconomic development and the women's movement, which have impacted various cultural structures and processes. Importantly, these factors have introduced transformation in social psychological orientations, and created novel modes of interpretation of, and greater flexibility in the adherence to, the traditional cultural rules for partner search and selection.

1. Theoretical Perspectives on Partner Selection

On what basis and how do people select partners for marriage? This question has elicited considerable scientific interest, and transcends disciplinary boundaries. Different disciplines have generated theories and models to study partner selection systems and strategies. In general, however, two major theoretical perspectives are evident: the evolutionary perspective and the social psychological perspective. A recent trend is to merge disciplinary perspectives and approaches in order to comprehend the complexities involved in partner search and achieve a clearer

understanding of the motives that determine the different elements of the process.

1.1 Evolutionary and Social Psychological Perspectives: Towards a Synthesis

Evolutionary theories enable understanding of the ultimate significance of heterosexual relationships, specifically the determinants of partner selection, whereas social psychological perspectives provide insight into the more proximate factors involved.

The evolutionary models of partner selection essentially view individuals as acting on the basis of evolved mechanisms, selected with a focus on maximizing ancestors' genetic fitness or increasing the likelihood of raising healthy offspring (Kenrick et al. 1993). These models contend that gender differences in preferences or selection criteria are cross-culturally universal, and have unfolded through sexual selection pressures over millions of years. As the physical condition of females is necessary for offspring survival, males generally tend to focus upon characteristics indicative of this aspect. On the other hand, females place more value on males' ability to contribute to resources.

A prominent theoretical model in social psychological perspectives on partner selection is the social exchange model, which posits that individuals search for partners who have resource value that is equitable with one's own 'market value.' In other words, there is an exchange of valued traits or resources (Kenrick et al. 1993). Based upon the market value of each trait, which varies cross-culturally, both women and men seek partners who will maximize gains and minimize costs. Social psychological models generally explain gender differences in terms of structural powerlessness of women and traditional sex role socialization patterns. Evolutionary theories, on the other hand, emphasize gender differences in terms of the reproductive investment hypothesis (Buss and Barnes 1986).

Evidence of the universality of certain gender differences in partner selection preferences across cultures supports the role that evolutionary forces play in shaping cultural factors that mediate the gender-based criteria for partner selection (Buss et al. 1990). Nevertheless, predictions related to psychological mechanisms in selection preferences offered by evolutionary models need to be viewed in conjunction with specific cultural-environmental contexts (see *Evolutionary Social Psychology*).

The sexual strategies theory proposes an integrated contextual-evolutionary perspective of partner selection. Based on the premise that human mating is inherently goal-directed, the theory incorporates factors from the larger context that have a bearing on partner selection and states that mating strategies are context-dependent in terms of the social milieu and the duration of the relationship. Also, the principles that govern selection by women and men are different and,

to that extent, the psychological strategies or mechanisms adopted to maximize reproductive success and offspring survival also differ (Buss and Schmitt 1993).

2. Culture as Mediator of Psychological Orientations

Culture is a significant mediating factor in partner selection. The cultural context provides shared schemas of meaning and knowledge systems that serve as a framework for individual experiences. The individual as a self-reflective and interpreting subject constructs and modifies the cultural schemas, thereby engendering transformation in the cultural rule systems for different domains, including partner selection. Thus, the cultural schemas on the one hand serve as a sort of template for individual and collective experiences, and on the other hand the individual constructs and modifies them in the course of cultural history (Eckensberger 1990) (see *Cultural Psychology*).

Social relationships and rule systems are at the core of culture. In cross-cultural psychology, these are conceptualized in terms of two main differentiations of self-concerned or other-concerned individual psychological orientations, related to Western and non-Western contexts, respectively (Markus and Kitayama 1991) (see *Cross-cultural Psychology*). The dichotomy of individualism and collectivism is commonly used to conceptualize the two types of cultures. Individualism emphasizes individual interests, needs, goals, and independence; collectivism refers to an orientation towards collective interests and norms with the aim to maintain social harmony (Hui and Triandis 1986) (see *Personality and Conceptions of the Self*).

The implications of these orientations for the structure and function of the primary social group, that is, the family, are of particular interest, in terms of the impact upon significant life events of individuals, including marriage and its integral process—selection of a partner.

3. Cross-cultural Perspectives

Multicultural studies of partner selection reveal interesting patterns of commonalities and diversities within and across cultures, which can be substantially attributed to changes in macro contexts as a result of industrialization and modernization.

Traditional and modern or collectivist and individualist cultures represent different clusters of qualities preferred in a prospective mate. Traits such as chastity, and domestic characteristics including desire for home and children, and being a good housekeeper are valued in traditional-collectivist cultures such as in China, India, Indonesia, Taiwan, Iran, the Palestinian Arab community, South Africa, and Colombia. The modern-individualist cultures (e.g., the USA, Canada, most of Western Europe)

consider such characteristics as irrelevant in the partner selection criteria or place a comparatively low value on the same. Relatively uniform gender differences across cultures are observed specifically in men's emphasis on physical appearance and value for traditional characteristics such as domestic skills, and women's emphasis on resource potential. Sexual dimorphism is evident most in the collectivist Asian and African cultures (Buss et al. 1990).

In the Western world, partner selection is essentially based on one's individual criteria, largely independent of familial and societal rules. Also evident is the growing utilization of innovative formal searching services. As one focuses on non-Western societies, specifically some selected Asian and African ones, the scenario reflects an interesting melange of 'traditional' and 'modern' (including Western) patterns in the process of partner selection.

The South Asian countries of China and Japan (Jew 1994, Wang 1994) demonstrate the continuance of certain traditional patterns of partner selection, such as arranged marriages, alongside the changes being introduced by Western influences. Individuals who marry are beginning to have more decision-making power. Nevertheless, parental opinion and approval are generally sought, if only as a mark of duty, obligation, and respect for them.

The ongoing transformation across the non-Western societies in particular, reveals the dynamic interface between culture and the self-reflective intentional individual who is engaged in the complex process of cultural reconstruction (see *Action Theory: Psychological*). Traditional normative rule systems provide a common frame for individuals' experiences of partner selection. In response to the larger context of rapid economic and social influences, individuals are engaging in a process of reinterpretation and reconstruction of the existing rule systems. In this context, societies that are predominantly characterized by collectivist perspectives are beginning to incorporate elements of the individualist perspective, in indigenized forms. The contemporary scenario illustrates a 'transitional phase' with varying blends of 'traditional' and 'modern' or 'collectivist' and 'individualist' perspectives and practices of partner selection represented cross-culturally.

4. The Indian Context

In Hindu India, marriage or *vivaha* is an inevitable significant life ritual (*samskara*). Marriage is considered as an alliance between two families, rather than two individuals.

4.1 Cultural Rules for Partner Selection and Emerging Social Psychological Orientations

Caste (*jati*) compatibility is the most important factor in a Hindu marriage. The position of the family in the

caste hierarchy determines the field of selection. This rule is now applied with greater flexibility, and there are incidences of intercaste marriages. A growing emphasis on individual characteristics of the prospective partner is also evident.

Although the arranged marriage remains a largely prevalent strategy of partner selection, the system has been modified to accommodate the preferences of adult children, and the traditional 'unconsented' model has given way to a 'consented' model (Banerjee 1999). The late 1990s also witnessed the growing involvement of external intermediaries, such as matrimonial advertisements and marriage bureaus, in partner selection.

The contemporary Indian context of partner selection reflects the influences of industrialization and modernization, including the global women's movement and the ensuing changes in values and accepted practices. These changes are revealed in the greater assertion of individual choice, the parallel instances of resistance to certain normative rules, and the diluting role of family and kin networks. Although the evolving climate is more conducive to the articulation of individualistic orientations, the value of family interdependence persists.

The Indian scenario depicts the continued resilience of traditional practices, alongside its adaptive features created to 'fit' with the transforming social context. It thus reveals the two-dimensional interdependent-independent or relational-autonomous orientation characteristic of many non-Western contexts (Kagitcibasi 1997).

5. Future Directions

How cultures operate to 'mate' individuals is a significant issue that provides a rich context for studying the interaction among psychological phenomena, their developmental patterns, and the cultural context. The emerging trend of integrating the social psychological or cultural and evolutionary models needs to be strengthened. Furthermore, indigenous paradigms for theory and research must be developed to trace the ongoing transitions and the diversity in developmental models across societies. Importantly, intracultural heterogeneity must be highlighted, especially in multicultural societies.

The validity of cross-cultural trends in specific gender-based selection preferences supported by the evolutionary model needs to be further corroborated. A critical question in this context is whether and to what extent women's education and economic independence actually enhance gender egalitarianism in the realm of partner selection. Importantly, interdisciplinary culture-based perspectives are imperative to develop conceptual frameworks for interpreting the wide-ranging diversity and complexity in the partner selection process.

Partnership Formation and Dissolution in Western Societies

1. Partnership Formation

1.1 Marriage Trends

In the recent past, marriage heralded the start of a first union for most couples in Western societies and the great majority of marriages survived intact until one of the spouses died. There tended to be identifiable stages

in the development of a relationship: courtship, engagement, and ultimately the marriage ceremony that was followed by the couple setting up home together. Nowadays, there is more flexibility in becoming a couple and whether they co-reside.

After World War II, the general trend in marriage behavior in European and other developed countries was towards a younger and more universal marriage pattern which reached its zenith during the 1960s and early part of the 1970s (Festy 1980, Espenshade 1985, Fitch and Ruggles 2000). Since then, marriage rates in most Western countries have declined (UN Demographic Yearbooks and Council of Europe demographic publications provide collections of relevant data). Younger generations have been marrying less, and among those who marry the trend has been to do so at older ages and over a wider range of ages than was common among their recent predecessors. In broad outline in the case of Europe, the decline in marriage rates began in Sweden and Denmark in the late 1960s, and then spread through most of Western Europe in the early part of the 1970s, and became evident in the southern European countries (Spain, Italy, Portugal, and Greece) around the mid-1970s. Since the 1980s, the decline in marriage rates continued in most European countries but at a slower pace. Changes in the mean age at first marriage provide an illustration of the extent of these changes. In 1975, the average ages of first-time brides in most Western nations were clustered in the 22–4 years range, whereas in the mid-1990s they were clustered in the range 26–9 years. The pattern of change was similar for men, but they marry, on average, two years older than women do, an age difference that has been fairly invariable over time.

1.2 Cohabitation

One of the important engines behind the decline in marriage rates and a movement to a later age at marriage is the rise in cohabitation that has occurred, particularly since the beginning of the 1980s in many countries and even earlier in Scandinavia. However, it should be emphasized that men and women living together outside marriage is certainly not new. Prior to the 1970s, it was largely statistically invisible and probably socially invisible outside the local community or social milieu. For example, in some European countries there were subgroups that were probably more prone to cohabitation than others: the very poor; those whose marriages had broken up but who were unable to obtain a divorce, as there was no such legislation, or it was more stringent than nowadays, or it was very expensive to obtain a divorce; certain groups of rural dwellers; and groups ideologically opposed to marriage.

The form of cohabitation that came to the fore during the 1960s in Sweden and Denmark, and during

the 1970s in other northern and Western European countries, North America, and Australia and New Zealand, is new, and has been variously termed 'premarital cohabitation,' 'nubile cohabitation,' and 'cohabitation juvenile'; in this form, young people predominantly in their 20s and early 30s live together either as a prelude to, or as an alternative to, marriage. Additionally, with the growth in divorce, 'postmarital cohabitation' has also become more prevalent, with the divorced cohabiting either in preference to, or as a prelude to, remarriage. Unfortunately, in many data sources, it is difficult to distinguish between the 'premarital' and 'postmarital' forms of cohabitation. However, the increased prevalence of cohabiting unions is likely to lie behind much of the decline in first marriage and remarriage rates that have occurred in many Western countries in the latter decades of the twentieth century.

Data on cohabitation has tended to be scarce and generally emanated from *ad hoc* surveys. This made comparative analyses problematic, as sample sizes, coverage, and definitions could vary. During the 1990s more information from standardized questionnaires became available from Eurostat (the Statistical Office of the European Communities) and from a series of Fertility and Family Surveys carried out in the main in the first half of the 1990s under the auspices of the UN Economic Commission for Europe (ECE) (United Nations 1992).

1.2.1 The incidence of cohabitation. Analysis of data from Eurobarometer Surveys carried out in the 15 member states of the EU in 1996 provides a perspective on the incidence of cohabiting and marital unions across a range of nations. These surveys are primarily opinion surveys covering a range of topics relevant to the EU, but they contain some very basic demographic information on the respondents, including information on marital status in which 'living as married' is one of the categories, the others being the more conventional ones of single, married, divorced, separated, and widowed. Such marital status distributions may not be as accurate as those obtained in dedicated family and fertility surveys, but they probably reflect the relative position of different European countries in these categories (European Commission, 1996).

Figure 1 shows the proportions of women aged 25–29 years in the 15 EU countries who were cohabiting, married, single, or separated/divorced/widowed at the time of the survey in 1996. In these data never-married and postmarital cohabitants cannot be distinguished, but it is reasonable to assume that at these younger ages the former is likely to be the most prevalent. It is clear from Fig. 1 that there is a good deal of diversity across European states in the incidence of cohabitation. Cohabitation is strikingly most common in the Nordic countries of Denmark,

Figure 1
Marital status distribution of women aged 25–29 in 1996

Sweden, and Finland, and France also has relatively high proportions cohabiting. There is also a middle group of countries, which includes The Netherlands, Belgium, Great Britain, Germany, and Austria with mid-levels of cohabitation. Data for the US and Australia suggest that they would fall into this middle group. At the other extreme is the set of southern European countries and Ireland, where cohabitation is seemingly much rarer with only a tiny minority cohabiting.

1.2.2 Type of first partnership. The UN ECE Fertility and Family surveys carried out in the main during the first half of the 1990s included a full partnership history that incorporated dates of marriages and any other co-residential heterosexual intimate relationships. Such histories permit more in-depth examinations of partnership formation and dissolution than can be gleaned from vital registration data or cross-sectional surveys that only include current status information.

In many Western nations there have been large increases in the proportions of couples cohabiting, and nowadays cohabitation rather than marriage marks the formation of a union. Evidence on this can be seen in Table 1, which shows for two recent cohorts of women the proportions who entered their first partnership at marriage. It is clear from these data that the younger women, those aged 25–9, were much less likely to have commenced their first partnership at marriage than the older women. There are marked reductions to be seen in the proportions of women who married directly without cohabiting in most countries; for example, in France 55 percent of the older women but only 21 percent of the younger women married directly, a pattern that is repeated across many of the nations. The main exceptions are Sweden and the southern European countries. In Sweden, cohabiting rather than marrying was already well established among the older women whereas in Italy and Spain there are indications of a rise in cohabitation; but for the majority of women marriage still heralds the start of the first partnership. This is in contrast with the Scandinavian and other Western European nations where it is a minority practice.

^a Nearest equivalent cohort

It is also the case that in many European countries cohabiting unions have simply replaced the marriages of yesteryear, in that compared with the recent past there has been little change in the proportions of men and women who have formed a residential partnership by their mid-20s, whereas in other countries (most noticeably the southern European states) cohabitation is only part of the story in the decline in marriage rates (Kiernan 1999). Here, young people have been spending longer periods of time as solos than in the recent past; living with their parents (in the main), on their own, or sharing with others (European Commission 1998).

1.2.3 Duration of cohabiting unions. In many developed countries cohabitation has eclipsed marriage as the marker for entry into the first union, but subsequently many of these unions convert into marriages and others dissolve. Life-table estimates of the proportions of cohabitations that had converted into marriages or dissolved five years after union formation for a range of European countries are shown in Table 2. There is some variation in the propensity to marry across nations and age groups. Sweden exhibits the lowest conversion to marriage, with only one in three cohabitations having become marriages within five years of the start of the partnership whereas in most other countries more than one in two cohabitations had converted into marriages by the fifth anniversary of the union. In several countries there are indications of a decline in the propensity to marry over time, most noticeably in Norway and France, whereas in other countries, such as Switzerland, there

is little sign of change. Turning to the extent to which cohabiting unions dissolve, we see from Table 2 that in most countries among those aged 25–9 years, around one in three unions had dissolved by the fifth anniversary of their start.

1.2.4 Who cohabits? In addition to cross-national variation in union-formation behavior, there is also variation within nations and between subgroups of the population (see Carmichael 1995 for a review). There is now robust evidence that in most nations the younger generations are more prone to cohabit than were older generations, and the more secular mem-

bers of a society and those who had experienced parental divorce during childhood are also the more likely to cohabit. There is also evidence that those residing in metropolitan areas are more prone to cohabit and that being in full-time education tends to inhibit union formation, but the association of level of educational qualifications and employment status with cohabitation is less clear-cut and tends to vary across nations.

1.2.5 A partnership transition? Many developed societies may be going through a transition in the way that men and women become couples or partners (Prinz 1995). Drawing on the experience of Sweden, which is the nation that has gone furthest in these developments, a number of stages can be identified (Hoem and Hoem 1988). To simplify, in the first stage, cohabitation emerges as a deviant or *avant-garde* phenomenon practiced by a small group of the single population, while the great majority of the population marry directly. In the second stage, cohabitation functions as either a prelude to marriage or as a probationary period where the strength of the relationship may be tested prior to committing to marriage, and this is predominantly a childless phase. In the third stage, cohabitation becomes socially acceptable as an alternative to marriage and becoming a parent is no longer restricted to marriage. Finally, in the fourth stage, cohabitation and marriage become indistinguishable with children being born and reared within both, and here the partnership transition could be said to be complete. Sweden, Denmark, and, to a lesser extent, France are countries that have made the transition to this fourth stage. These stages may vary in duration, but once a society has reached a particular stage it is unlikely that there will be a return to an earlier stage. Moreover, once a certain stage has been reached, all the previous types of cohabiting unions can co-exist. Such stages also have parallels at the level of the individual. At any given time, cohabitation may have different meanings for the men and women involved; for example, it may be viewed as an alternative to being single, or as a precursor to marriage, or as a substitute for marriage. Moreover, how a couple perceives their cohabitation may change over time and may also vary between the partners. Dissecting cohabitation in this way highlights the diversity of the phenomenon and suggests that more so than marriage it is a process rather than an event.

In sum, analyses of recently available data on union formation show there to be marked variation in the ways men and women are forming partnerships across developed nations. In the 1990s marriage was still the pre-eminent marker for entry into first union in the southern European countries, whereas in most Western European countries, and in North America, and Australia, and New Zealand, cohabitation has eclipsed

marriage as the marker for first partnership. Notably, in the Nordic countries, long-term cohabitation has become more prevalent. Most Western countries appear to be experiencing changes in the ways that men and women become couples, but the question of whether most countries are on a trajectory to an ultimate destination where marriage and cohabitation are largely indistinguishable or even where cohabitation overtakes marriage as the dominant form of union awaits the future for an answer.

2. Partnership Dissolution

2.1 The Rise of Divorce

The other major development in partnership behavior is the rise of divorce. This has brought to the fore fundamental issues about the roles of men and women in society and the care and support of children. In most Western nations death still terminates the majority of marriages, but over the last few decades marriages have been increasingly dissolved by divorce before death has made any significant inroad and at a stage in the marriage when there are likely to be dependent children. In most Western countries divorce has increased since the mid-1960s, following a period of very stable divorce rates throughout the 1950s and the early part of the 1960s. Figure 2 shows trends since the early 1970s in the extent of divorce as measured by the number of divorces per 1,000 population for a range of Western countries. At the beginning of the 1970s the highest divorce rates were to be found in the US, and in Denmark and Sweden among countries in Europe. Divorce rates increased during the 1980s in most countries, and since then the rates have stabilized in many countries. Between 1960 and the mid-1980s divorce policy was either completely revised or substantially reformed in almost all the Western countries (Phillips 1988). Most countries liberalized their divorce laws, moving from fault-based divorce to no-fault divorce laws whereby fault, responsibility, or offense was no longer attributed by the law to either spouse. Following the liberalization of divorce laws, divorce rates in many countries continued their upward trend, frequently at a faster pace than in the years preceding legislative changes, followed by a period of stabilization from the mid- to late 1980s.

In the mid-1990s there was still a good deal of variation in the level of divorce across Western nations. In 1995 the total divorce rate in the EU was 0.30, whereas in 1970 it had stood at 0.11 (Eurostat 1997). This indicator is an estimate of the mean number of divorces per marriage for a notional cohort subjected to current divorce rates at each marriage duration. It can broadly be interpreted to mean that if the propensity to divorce remained unchanged over time, 30 percent of marriages would end in divorce. If

Figure 2

Crude divorce rates: divorces per 1,000 population

current rates were to prevail, nearly one in three marriages in the EU would dissolve. This is a lower level than in Canada (44 percent) and the US, where the total divorce rate has been above 50 percent since the late 1970s. Within Europe there is also a good deal of diversity in the level of divorce. During the 1990s three distinct divorce regions can be distinguished. In the Nordic countries and in England and Wales, the total divorce rate has been consistently above the 0.40 level. In Western European nations (Austria, Switzerland, Germany, France, Belgium, Netherlands, Iceland, and Luxembourg), the indicator lies between 0.30 and 0.40. In the southern European countries (Greece, Portugal, Spain, and Italy) it is below 0.20.

Divorce statistics have invariably underestimated the totality of marital dissolutions, and with the rise of cohabitation even fewer partnership dissolutions are captured by divorce registration data. In countries where divorce is more long-standing and more prevalent, there has been a tendency for marriages to break-up sooner. As a consequence, more couples are likely to be childless, and among couples with children the children are likely to be younger. Rising divorce has

led to a growth in lone-parent families, the residential separation of fathers from their children, and remarried couples and stepfamilies.

2.2 Lone-parent Families

The prevalence of lone parenthood varies considerably between countries, and the proportion of families headed by a lone parent has been increasing just about everywhere, as can be seen in Table 3. As yet, no Western European country has matched the US, where more than one in four families with children are lone-parent families. Various reports made for the EU (for example, Bradshaw et al. (1996) show that the great majority of lone-parent families are headed by a woman (80–90 percent). The largest group of lone parents comprises those who have experienced a marital breakdown, the next largest group comprises widows, and lone mothers who had never been married (but not necessarily never partnered) are the smallest category. In many countries where there have been

marked increases in childbearing outside marriage (but again not necessarily outside a partnership, see *Fertility of Single and Cohabiting Women*), this ordering may well have changed, such that never-married women with children may now constitute the second largest group of lone-mother families. Overall, the majority of lone-parent families emanate from the break-up of partnerships, either marital or cohabiting ones.

There is a good deal of evidence that children who experience the break-up of their parents' marriage or nonmarital union are more likely to experience poverty or reduced economic circumstances than children who grow up with both natural parents, but that the depth of poverty varies across nations (Bradshaw et al. 1996). The financial exigencies associated with marital breakdown arise from the precarious economic position of lone mothers, with whom most children live, and the dis-economies of scale associated with the maintenance of two households when fathers live apart from their children. The low incomes of lone-mother families are due to a combination of factors: low earnings from employment, lack of or low levels of child support from the natural father, and inadequate state support.

2.3 Remarriage

Being reared by a lone parent is frequently not a long-term arrangement, as a substantial proportion of divorced persons eventually remarry. Men are even more likely than women to remarry and are also more likely to remarry more quickly after a divorce. As well as being more likely to remarry, divorced men are more likely to cohabit than are divorced women.

Remarriages are also at greater risk of dissolution than are first marriages. After an initial upsurge in remarriage rates in the early years following the enactment of more lenient divorce legislation, which occurred in most European countries, remarriage has taken a downturn due to some extent to postmarital cohabitation becoming more common.

2.4 Children and Divorce

Parental divorce and its aftermath constitute a major factor in the collective make-up of the generation of children born since the 1970s in northern European countries, as they did for the generations born since the 1960s in the US, and from whose experiences much of our knowledge on this topic emanates. This factor is increasingly being experienced by the generation born during the 1980s in many other European countries. Parental separation has been shown to affect the lives of children in both the short and long term (Amato and Keith 1991a, 1991b). Following their parents' separation, children frequently go through a crisis, during which behavior problems at home and at school are more often reported, worries become more prevalent, and anxiety levels increase. After divorce, families may have to move house through necessity rather than choice, which in turn leads to changes in schools, and neighborhood and social networks. Poverty or at least reduced economic circumstances are likely to be a prominent feature of these children's lives.

A number of studies from a range of countries have shown that children who experience the breakup of their parents' marriage subsequently have lower educational attainment, receive lower incomes, and are more likely to be unemployed and to be in less prestigious occupations in adult life than their contemporaries brought up by both parents (Jonsson and Gähler 1997, McLanahan and Sandefur 1994). In the demographic domain, young women who have experienced parental divorce are more likely than their peers to commence sexual relations early, to cohabit or marry at young ages, to bear children in their teens, and to conceive and bear children outside wedlock (Kiernan and Hobcraft 1997, McLanahan and Sandefur 1994). Men and women from disrupted families are also more likely to experience the breakup of their own marriage (Glenn and Kramer 1987, Kiernan and Cherlin 1999).

3. Conclusion

Across many Western nations there have been dramatic changes in partnership behavior, most noticeably the rise of cohabitation and divorce. The general direction of change in most Western countries is similar but there continues to be marked variations

across nations (and probably within nations) in the extent to which these developments have taken hold. Marriage once signaled the start of a lifetime partnership for the great majority of couples, but it is increasingly being replaced by more flexible and contingent partnerships that have no formal commencement and that continue only as long as both partners derive satisfaction from the relationship. A range of sociological and economic explanations has been posited to account for these changes (see *Family Theory: Complementarity of Economic and Social Explanations*).

Party Identification

Party identification is one of the central explanatory concepts used in the analysis of voting behavior in mature democracies. It refers to the enduring affective (emotional) attachment a voter feels towards a particular political party which disposes him or her to vote for that party in elections. Republican 'identifiers,' for example, are much more likely than other voters to vote Republican in a range of different elections; Democrat identifiers are similarly more likely to vote Democrat. A distinction is sometimes made between 'strong' and 'weak' identifiers, depending on the strength of the individual's attachment to the party in question. Both of these groups are contrasted with 'floating' or 'independent' voters, who exhibit no obvious attachment to one party over time and who frequently switch their votes between parties at succeeding elections. Party identification is sometimes referred to as 'partisanship.' The two terms are used interchangeably here.

1. Intellectual Context

The concept of party identification was originally developed as an integral part of the Michigan social psychological model of voting behavior. Partly through socialization experiences in childhood and in the workplace, individuals come to feel that their own political beliefs and values are 'closer' to the core ideological and policy positions of one party rather than another. Some individuals will enter adulthood as fully fledged 'identifiers' with a particular party. For others, the process may take longer. But the more frequently that an individual votes for a particular party over time, the more likely it is that s/he will come to 'feel closer to' or 'identify with' that party: s/he will

become a 'party identifier.' This, in turn, will reinforce the individual's tendency to continue to vote for the party, even when other factors might militate against it.

Although party identification is primarily a psychological concept, it also has a direct counterpart in rational choice theory in Downs' concept of the 'standing vote.' According to Downs, voters can develop a habit of voting for one party as a way of reducing the costs of continuously collecting and evaluating political information. Relatively early in their political lives, they make judgements about which party is closest to their own ideological positions and tend subsequently to continue to support that party unless and until some major political trauma causes them to reassess their early judgement. Fiorina's work on voting in the USA goes some way to combining the psychological notion of affective attachment with Down's idea of the standing vote. Fiorina argues that party identification is best seen as a running tally, or cumulation, of voters' retrospective evaluations of the major parties. In short, identification results from a voter's perception that a particular party has outperformed its rival(s) over time; it disposes the voter to support that party in the current election.

2. *Emphases in Current Theory and Research*

The concept of party identification has been deployed in four main ways. The first, and most extensive, use is as a 'nonproximate' cause of vote choice. Voters are obviously swayed by a variety of different factors in deciding how to cast their votes in elections. These include voters' perceptions of any triumphs or disasters that occur in the final weeks of a campaign; their perceptions of the candidates' character; their views of the policy stances of the parties; and their assessments of the parties' performance in office and in opposition.

For advocates of the party identification approach, a crucial additional factor is the extent to which voters are predisposed—independently of any of the above 'proximate' factors—to support one or other of the parties because they 'identify' with it. On this account, the effects of proximate causes of the vote can only be properly estimated if the underlying effects of voters' prior partisan identifications have been fully taken into account. Concomitantly, explanations of voting choices (and election outcomes) that underplay the importance of long-term party identifications risk overstating the significance of the more proximate factors that explain voting choices. In all this, there is no suggestion that party identifiers always vote for the party with which they identify. On the contrary, it is entirely possible for even strong identifiers on occasion to vote against 'their' party because other more proximate factors weigh more heavily in their vote calculations. In US presidential elections, for example,

between five and twenty percent of identifiers typically vote 'against' the party they identify with. For these voters, party policies, party performance or the leadership qualities of the rival candidates (or some other proximate factors) must have weighed more heavily than traditional party loyalties. Party identification theory argues, however, that in subsequent elections 'defecting identifiers' are highly likely, other things being equal, to bring their voting behavior back into line with their partisan identity; they return to their traditional partisanship.

The second usage of the concept of party identification follows from the first. If prior identifications dispose citizens to vote in particular ways, then those identifications are also likely to color the way in which voters interpret political information. Party identification in this sense acts as a framing factor—a sort of perceptual filter—which disposes voters to view *their* party's policies, its leaders, and its record in a more favorable light than might otherwise be the case. It simultaneously disposes voters to view *other* parties' characteristics less favorably. This implies that voting choices are not only affected *directly* by party identification. These choices are also affected *indirectly* because of the 'coloring' effects of identification on voters' perceptions of the parties' competing attractions—perceptions which in turn also influence the way people vote.

A third use of the concept of party identification is made by the political parties themselves in devising electoral strategy. Party strategists are always aware of the need both to mobilize their party's own identifiers and to appeal to those voters who in the past have not been inclined to lend the party their support. In the early stages of a campaign, the main task is to trigger the support of existing partisans; in later stages it is to convert neutrals and those who identify with competing parties. Measures of party identification give strategists some idea of the size of their 'core vote.' This is the minimum level of support that parties can expect to obtain in a general election and against which, once the election outcome is known, their strategists can judge their success in recruiting new supporters. The need to provide participants in the democratic process with accurate information about their performance puts a particular premium on the accuracy of estimates of partisanship levels. For this reason debates about the measurement of party identification (which are discussed below) involve more than just matters of academic interest.

The final usage of the concept of partisanship is as a phenomenon in its own right that requires analysis and explanation. To argue, as party identification theory does in relation to any given election, that a major reason why voters vote Republican or Democrat—or Conservative or Labour—is that they are already Republican or Democrat, identifiers does not, on the face of it, seem to explain very much. Indeed, it borders on the tautological. The notion that 'I vote

Republican because I am a Republican identifier' immediately begs the question as to why I identify with the Republicans in the first place. As implied above, party identification theory's answer to this question is that partisanship develops as a result of long-term exposure to a variety of socialization processes in the individual's family, school, workplace, and social milieu.

Note, however, that socialization experiences of this sort fail to provide an obvious explanation as to why some voters *switch* their identifications (from Republican to Democrat or from Labour to Conservative, for example) midway through their voting lives. Fiorina's notion of identification as a cumulative updating of retrospective assessments of party performance plays a useful explanatory role in this context. Consider a voter A who, as a result of childhood and early adult socialization experiences, identifies with—and accordingly votes for—the Conservatives at election e1. Assume further that the Conservatives appear so incompetent at the subsequent elections e2 and e3 that A switches his vote to Labour on both occasions. In these circumstances, A may also shift his identification to Labour to reflect the fact that his 'running tally' of retrospective performance now favors Labour rather than the Conservatives. Although Fiorina's analysis does not predict the precise point at which voters will switch their identification from one party to another, it offers a plausible explanation as to how, notwithstanding their early political socialization, voters can change their identifications over time.

3. *Methodological Issues: The Problem of Measurement*

A key methodological issue concerns the extent to which the party identification measures developed in the USA in the 1950s can be successfully transplanted to other political contexts. Data from successive US National Election Studies (NES) suggest that roughly three-quarters of US voters are either Republican or Democrat identifiers (the remaining quarter are 'independents') and that substantial proportions of voters retain their partisan identities over time. Given that these findings are consistent with the idea of party identification being both widespread and durable, the concept of partisanship has maintained a prominent position in analyses of electoral outcomes and electoral change. Indeed, most published accounts of US voting behavior include either controls for, or estimates of, the effects of partisanship on the vote.

Not surprisingly, when efforts have been made to extend the theories and methods of the NES to other countries, the concept of party identification has been 'exported' as a central part of the package. An early example was the inclusion of a party identification question in the 1964 British Election Study (BES)

survey. The question was borrowed directly from the NES and it has been employed with only minor variations in question-wording since:

Generally speaking, do you think of yourself as Conservative, Labour, Liberal-Democrat, (Nationalist) or what?

The phrase 'generally speaking' is intended to tap the idea that party identification—as opposed to the more immediate and ephemeral notion of current party preference—endures over time; 'think of yourself' attempts to capture the respondent's political identity.

Most analysts of British electoral politics would endorse the idea that party identification plays an important role in explaining UK voting decisions. However, considerable doubt has also been expressed as to whether the traditional partisanship question measures anything very different from voters' current party political preferences. There are two major reasons for supposing that it does not. First, responses to the standard question outlined above suggest that, since the 1960s, 90–5 percent of British voters have had some sort of party identification. This is clearly a much higher level of 'measured' partisanship than in the USA, which should in turn imply much greater stability over time in British voting patterns. Yet electoral volatility since the 1970s has not been noticeably lower in the UK than in the USA. Second, it is clear from British data that major shifts in party identification levels (in 1979, 1983, and 1997) have coincided exactly with major shifts in voting behavior—implying that both, perhaps, are indicators of current political preferences rather than separate phenomena. This conclusion is supported by monthly time-series data collected by Gallup which show that short-term fluctuations in British partisanship correlate very strongly with short-term changes in party support levels. More formal tests, based on the principles of 'convergent validity' indicate that, in Britain at least, extant measures of party identification are statistically indistinguishable from measures of voting preference. This in turn implies that models of vote choice which include party identification as an explanatory variable are tautologically mis-specified.

Although these difficulties have not been precisely replicated in all of the countries where partisanship measures have been deployed, similar problems have been encountered in a variety of different national contexts. As a result, many analysts outside the USA have expressed concern that in non-American contexts (where the concept of the 'political independent' is less well developed) the standard NES question invites respondents to admit to a partisan identity even when they do not have one. This has led a number of researchers to advocate the use of a 'filter' mechanism in measuring partisanship, such as the following:

I am now going to ask you a question about party politics in [country]. Some people think of themselves as usually being a

supporter of one political party rather than another. Setting aside your current views about the government and opposition parties, do you usually think of yourself as being a supporter of one particular party or not?
If YES, which one is that?

The key feature of the filter is that it allows survey respondents to indicate from the outset that they do *not* usually think of themselves as being supporters of a particular political party. Survey experiments using filters of this kind have been conducted in Canada, the UK, the USA, and elsewhere. The measured levels of party identification fall considerably as a result. In Canada, switching from the traditional question to the filter approach reduces measured party identification levels from 70 percent to 40 percent of the electorate; in the UK, identification falls from around 90 percent to under 50 percent; and in the USA it falls from roughly 70 percent to 60 percent. The effects of using a filter, in short, are very considerable outside the USA, implying that levels of party identification in other countries may have been significantly overestimated in much academic research where the traditional NES question has been imported for local use. This is obviously important in purely descriptive terms but it also suggests significant measurement error problems in any statistical models that (outside the USA) have used party identification measures.

The problems of measuring party identification effectively do not stop here, however. A critical feature of partisanship is that it is, for the individual voter, an enduring feature of his or her political makeup. Partisanship should therefore be quite stable at the individual level over time, which implies that an individual should respond to the party identification question in a consistent way over time. Since 1991, the British Household Panel Survey (BHPS) has been collecting annual data on party identification in the UK using the sort of 'filter' question outlined above. In every wave of the panel, under 50 percent of respondents have indicated that they have a party identification. In the general election year of 1997, for example, 28 percent of the sample were Labour identifiers, 14 percent were Conservative identifiers, and 4 percent Liberal Democrat identifiers. As intimated earlier, these levels are clearly much lower than those recorded on the basis of the traditional NES question wording. But the measurement problem extends much further than this. Party identification is supposed to be a stable and enduring characteristic of individual voters. The BHPS reinterviews the same respondents in successive annual waves of the survey. We can therefore inspect the data to see how far individuals retain the same party identifications over time. As Table 1 shows, even if we consider only a 3-year 'rolling window' (i.e., we consider voters responses in waves 1–3, then waves 2–4, then 3–5, and so on), the levels of consistent identifiers fall even further. For example, in waves 1, 2, and 3 (1991–1993) only

Table 1

Percent of BHPS respondents with consistent and inconsistent party identifications over successive three-year periods, 1991–7

	W1–3	W2–4	W3–5	W4–6	W5–7
Consistent					
Conservative	9.5	8.9	7.6	7.4	6.9
Consistent					
Labour	7.9	9.4	10.5	11.1	12.5
Consistent					
Lib Democrat	1.3	1.1	1.0	0.9	1.0
Inconsistent	52.1	50.2	46.8	43.2	45.8
Non-identifier	29.2	30.4	34.1	37.4	33.8

Source: British Household Panel Survey

9.5 percent of respondents consistently responded as Conservative identifiers and only 7.9 percent consistently as Labour identifiers. In waves 5, 6, and 7 (1995–7), only 6.9 percent were consistent Conservative identifiers and 12.5 percent Labour identifiers. The remainder (excluding the trivial number of consistent Liberal Democrats) were either consistent nonidentifiers (33.8 percent) or else switched identifications across waves (45.8 percent). In short, only around 20 percent of British voters in the 1990s were 'genuine' party identifiers in the sense that the measuring instrument used: (a) allowed them to indicate from the outset that they had no particular attachment to any party; and (b) required them to declare the same general partisan commitment on three (and only three—the figures are even lower if the length of the rolling window is extended!) successive occasions.

Where does this leave us? Party identification is a theoretical construct that makes a great deal of intuitive sense. It tells us that individuals have long-term, enduring attachments to political parties and this idea in turn helps us to understand why individuals often vote for the same party in successive elections. Yet when we try to measure partisanship, things become far less clear. Generations of American scholars have happily employed the concept, confident that the NES question wording effectively captures the enduring nature of the partisan's affective commitment to his or her party. However, data from other countries—and especially from Britain—casts considerable doubt on the use of the concept in other national contexts. In the UK, large numbers of voters—much larger than are revealed by the NES question—appear to have no commitment to any political party. And of those that do, less than 20 percent retain that commitment over a three-year period. In short, if party identification denotes an *enduring* affective attachment to a particular political party, then partisanship in the UK at least is very much a minority predisposition.

Future research which seeks to employ the notion of party identification will need to address two major issues. The first, discussed above, is the need to develop operational empirical measures of the concept that are both durable and have substantive meaning in the specific national contexts in which they used. Critically, these new operational measures must distinguish effectively between voting choice and partisanship. The second issue concerns the impact of the longer-term process of 'partisan dealignment.' It is generally acknowledged that, however partisanship is measured, levels of party identification have gradually fallen in most democracies since the 1970s. Electorates have become increasingly volatile and voters increasingly prepared to behave like 'electoral consumers,' picking and choosing between parties on the basis of the rival policy and leadership packages on offer. In these circumstances, as Fiorina observed, partisan attachments acquired early in voters' political lives are likely to be less important in determining voting choices than the more temporary 'brand loyalties' associated with the perception that 'party X currently appears more competent in managerial terms than party Y.'

Party Responsibility

Party responsibility is the attribution of collective responsibility to the political party in power for the performance of government. This contrasts with the attribution of individual responsibility to particular officeholders for their performance in office. Party

responsibility is the core idea of a model, known as responsible party government, of how democratic government should be organized in a modern populous nation.

1. The Party Government Model

The party government model was first developed by the American writers Woodrow Wilson, Frank J. Goodnow, A. Lawrence Lowell, and Henry Jones Ford in the last two decades of the nineteenth century, and served as a base for criticizing the existing American parties and proposing party reform. It lost favor in the Progressive Era and languished until the 1940s, when it was revived by another generation of American writers led by E. E. Schattschneider in *Party Government* (1942) and *The Struggle for Party Government* (1948), with support from Herman Finer in *The Theory and Practice of Modern Government* (1932) and James MacGregor Burns in *The Deadlock of Democracy* (1963). Its visibility was maximized in 1950 with the publication of *Toward a More Responsible Two-party System*, a report of the American Political Science Association's Committee on Political Parties.

The model is based on the proposition that democratic responsibility depends on the possession and exercise of power. If an individual or group does not control the actions of government, a sovereign people cannot effectively hold that individual or group responsible for those actions. Democratic governments in modern populous nations cannot be controlled by individual officeholders, not even US presidents. A member of Congress has only a small share of the total power over government, and he or she can be held responsible only for his or her votes and speeches, not for the performance of the entire government. Even the president cannot control the actions of Congress or the Supreme Court, and so cannot meaningfully be held responsible for governmental performance.

The only entity large enough to control the entire government and public enough to be held responsible for what it does or fails to do is a political party. Therefore, only the collective responsibility of the majority party can establish effective popular control of government.

The model has three basic requirements. (a) The parties must have near-perfect cohesion on all public issues: the members of each party must act together so that they can be held collectively responsible. (b) The voters must vote for a preferred party's candidates as representatives of the collectivity, not as isolated individuals. (c) The winning party must control the entire power of government, so that it can reasonably be held responsible for the government's actions and inactions.

Ideally, the model of responsible party government should work like this: at least two (and, preferably,

only two) unified, disciplined major political parties exist. In a pre-election campaign, each sets forth its proposals for measures to deal with the nation's problems, and the differences between the two sets of proposals are great enough to provide the voters with a meaningful choice. In the election the voters vote for certain candidates for Congress and the presidency or for Parliament, *not* because of their individual eloquence and probity, but because they are members of the party the voter thinks should control the government for the next term. One party receives a majority of the votes and public offices, and takes over complete governmental power and therefore assumes complete responsibility for what government does or fails to do. At the end of its term the voters decide whether the governing party's record is mainly good or bad. If they like it, they vote to return it to power. If they dislike it, they vote to replace it with the other party, which has pointed out the governing party's errors, and stands ready to take its place.

The doctrine's advocates generally present it as a model, a theoretical construct, the merits of which are to be assessed by theoretical reasoning and discourse. They do not wish its merits to be determined by how well or badly any actual governmental system performs. However, it is clear that most of them regard the government and party system of the United Kingdom as close enough to the model to provide a basis for answering questions about how the model would actually work in a nation like the United States.

2. *The Model Used*

From its origins the model of responsible party government has been used mainly to highlight certain perceived failings of the American party system and to prescribe remedies. Three such failings have received the most attention: first, the parties do not stand for anything. As Woodrow Wilson put it,

Provided with parties in abundance, and entertained with very nice professions of political principle, we lack party responsibility. American parties are seldom called to account for any breach of their engagements, how solemnly soever those engagements may have been entered into ... 'Platforms' are built only for conventions to sit on, and fall into decay as of course when conventions adjourn. Such parties as we have, parties with worn-out principles and without definite policies, are unmitigated nuisances. (*Committee or Cabinet Government?* Wilson 1925, p. 109)

Some commentators of Wilson's persuasion said that the American major parties are like bottles bearing different labels but equally empty.

They are uncohesive and therefore irresponsible. Votes in Congress rarely fall along strict party lines, and so it is impossible for voters to tell what each party—as distinct from its individual members—has

done on the issue. Hence, neither party can meaningfully be rewarded for good governmental actions or punished for bad ones. As a result, the American people can choose only between an incumbent officeholder and his or her opponent, neither of whom has much power over—and therefore cannot assume responsibility for—the actions of government. As the American Political Science Association (APSA) committee put it, the American party system consists largely of 'two loose associations of state and local organizations, with very little national machinery and very little internal cohesion ... [both of which are] ill-equipped to organize [their] members in the legislative and executive branches into a government held together and guided by the party program' (American Political Science Association, Committee on Political Parties 1950, p.v).

Some critics of the APSA report pointed out that the American constitutional system is an insurmountable barrier to the achievement of party government. Especially the institutions of separation of powers and federalism make it impossible for one party, by winning a majority of the votes and offices in any single election, to get full power over all governmental machinery and assume responsibility for what it does or fails to do.

Some advocates of party government, however, were not impressed. Schattschneider pointed out that in the past parties have had great success in making changes in the constitutional system without altering a word in the Constitution—for example, in the reshaping of the Electoral College system for electing the president—and he concluded that there are no 'grounds for excessive pessimism about the possibilities of integrating party government with the constitutional system. The greatest difficulties in the way of the development of party government in the United States have been intellectual, not legal. It is not unreasonable to suppose that once a respectable section of the public understands the issue, ways of promoting party government through the Constitution can be found' (Schattschneider 1942, pp. 209–10). The APSA Committee added that when the electorate becomes convinced that responsible parties are the best device for achieving popular control of government, the battle will be largely won, for the voters will insist that each party act together cohesively in a truly responsible manner.

3. *The Model Criticized, the Parties Defended*

From its beginnings the responsible party government model has had its critics. Perhaps the most prominent early opponent was Moisei I. Ostrogorski, a Russian writing in French. He first wrote an analysis of the British party system (especially interesting because it attacked the system often hailed as the working model

of responsible party government). His basic charge was rooted in his belief that the only meaningful form of democratic responsibility is the individual responsibility of each elected representative to his or her constituents. The worst thing about the British system, he said, is that 'the ministers ... easily hide behind the collective [party] title; however incompetent or culpable they may be, it is impossible to punish one of them without punishing all ...' (Ostrogorski 1902, I, p. 716).

His later (1910) volume on American parties charged them with many sins, of which the worst is that they are permanent conspiracies of political bosses interested only in winning elections so as to control government patronage. They have no interest in policy issues, and the voters cannot affect the course of public policy by voting for one party or the other. The only solution is to restore parties to what they were originally intended to be: *ad hoc* assemblies of like-minded citizens concerned with a particular policy issue, which will dissolve when that issue is settled.

The debate about what role parties should play in America and how they should be organized to play that role lay dormant until 1940, when E. Pendleton Herring published *The Politics of Democracy*. Herring argued that the unreformed parties had performed many valuable functions for American government and society, notably overcoming the potential for total gridlock inherent in separation of powers and federalism, stimulating ordinary people's interest and participation in politics, and moderating the ferocity of interest groups' demands by aiming their platform compromises and electoral appeals at the members of as many interest groups as possible rather than standing firmly and clearly for the interests of a restricted number of groups and the total rejection of those of other groups.

Herring's lead was followed by the authors of several works stimulated by *Toward a More Responsible Two-party System*. Political scientists Julius Turner and Austin Ranney argued in the *American Political Science Review* that the doctrine of responsible party government makes sense only in a democracy whose people are firmly committed to the implementation of unlimited majority rule, while in fact the American people have shown that they are more committed to the protection of minority rights. This explains why ordinary Americans have been so resistant to adopting the responsible party government model and its features of party discipline and cohesion and so admiring of individual independence in their officeholders. This same argument was developed at greater length in Ranney and Kendall's textbook *Democracy and the American Party System* (1956).

These defenders of the existing parties did not, however, silence the doctrine of responsible party government. The Schattschneider position was carried on and updated by, among others, the political scientist James MacGregor Burns (1963) and the journalist David Broder (1972). Moreover, since the

1970s both parties in Congress have become noticeably more cohesive and ideologically more distinct than they were in Schattschneider's (or Ostrogorski's) time. On the other hand, the proportion of voters voting split tickets has increased (to about 25 percent in the 1996 elections), and one of its main consequences, divided party government, with one party controlling the presidency and the other controlling one or both houses of Congress—a situation incompatible with responsible party government—has become the rule rather than the exception.

The net result is that while parties and officeholders in some parts of the national government are behaving more as the model requires, the voters' weakening party loyalties and increasing tendency to vote for individual candidates with little regard for their party labels are behaving less so. The dispute between the model's advocates and critics continues, but the party system changes only in some parts and in opposite directions.

Party Systems

A party system is the system of interactions between political parties that results from their mutual competition or cooperation (see Sartori 1976, p. 44). For party systems to exist there must therefore be more than one party involved. One-party states do not have party systems. Beyond the requirement for a plurality of parties, party systems can be said to exist only when these interactions between the parties are patterned, familiar, and reasonably predictable. A plurality of parties is therefore a necessary but not sufficient condition for the existence of a party system. Parties that exist alongside one another, but that do not interact in any patterned or structured fashion, do not make for a party system as such.

While it may seem difficult to conceive of situations in which a plurality of parties exists without at the same time embodying a set of patterned interactions, two types of limiting cases can be identified. The first is where each of the parties involved exists in an entirely self-sufficient world, based on a closed electoral constituency, with neither its survival nor performance being in any way effected by the other parties in the polity. Even in this limiting case, however, the absence of interactions at the electoral level might well be accompanied by the need to interact—through competition or cooperation—at the parliamentary or governmental level. Thus, while no electoral party system would exist, it might well prove possible to speak of a party system in parliament. The

second type of limiting case is where a new multiparty democracy is being established more or less from scratch, such as in the wake of a democratic transition, and where neither the new parties themselves, nor their interactions, have stabilized sufficiently to allow the identification of a distinct pattern. In these situations, a party system may be in the process of being structured or institutionalized but it cannot yet be said to have definitely emerged. In their survey of party systems in Latin America, Mainwaring and Scully (1995) adopt a similar distinction in specifying party systems as either ‘institutionalized’ or ‘inchoate.’ Strictly speaking, however, an inchoate or non-institutionalized party system is a contradiction in terms: to be a system is to be institutionalized.

1. Classifying Party Systems

Although scholars have paid relatively scant attention to what defines a party system as such, tending instead to assume the existence of a party system in all polities where there exists a plurality of parties, they have devoted considerable effort to distinguishing between different types of party system. The most conventional and frequently adopted approach to distinguishing party systems is based simply on the number of parties in competition, and the most common distinction involved here, which goes back to Duverger (1954), is very straightforward—that between two-party systems, on the one hand, and multiparty (i.e., more than two) systems, on the other. This particular classification was also believed originally to reflect a more fundamental distinction between more or less stable and consensual democracies, such as the United Kingdom and the United States, which were seen as typical of the two-party variety, and more or less unstable or conflictual democracies, such as Fourth Republic France, Italy, or Weimar Germany, which were seen as typical of the multiparty type. Although this simple association of numerical categories of party system with levels of political stability and efficacy was later undermined by reference to a host of smaller democracies that were characterized by both a multiplicity of parties and a strong commitment to consensual government, the core distinction between two- and multi-party systems has continued to be widely employed within the literature on comparative politics, although it is sometimes modified by taking into account not only the sheer numbers of parties in competition, but also their relative size. Thus, Blondel (1968), for example, uses the relative size of the parties to distinguish four types of party system: two-party systems, two-and-a-half-party systems, multiparty systems with a dominant party, and multiparty systems without a dominant party.

The most substantial attempt to move away from a primary reliance on the simple numbers of parties in competition was that of Sartori (1976, pp. 117–323),

who combined counting the parties with a measure of the ideological distance that separated them. Sartori's typology was the first that focused directly on the interactions between the parties—the 'mechanics' of the system—and hence on the differential patterns of competition and cooperation. Following this approach, party systems could be classified according to the number of parties in the system, in which there was a distinction between systems with two parties, those with up to some five parties (limited pluralism) and those with some six parties or more (extreme pluralism); and according to the distance that separated the parties lying at either extreme of the ideological spectrum, which would either be small ('moderate') or large ('polarized'). These two criteria were not wholly independent of one another, however, in that Sartori also showed that the format of the system, that is, the number of parties, contained 'mechanical predispositions,' that is, it could help determine the ideological distance, such that extreme pluralism could lead to polarization. When combined, the two criteria resulted in three principal types of party system: two-party systems, characterized by a limited format and a small ideological distance (e.g., the UK); moderate pluralism, characterized by limited or extreme pluralism and a relatively small ideological distance (e.g., Denmark or the Netherlands); and polarized pluralism, characterized by extreme pluralism and a large ideological distance (e.g., Weimar Germany, early postwar Italy, or pre-Pinochet Chile). Sartori also noted the existence of a 'predominant-party system,' in which one particular party, such as, for example, the Congress party in India, or the old Unionist party in Northern Ireland, consistently won a winning majority of parliamentary seats.

2. Party Systems and Structures of Competition

At the core of any party system is the competition for executive office. It is this that structures the party system in the first place, and facilitates its institutionalization. Moreover, albeit often implicitly, the competition for executive office is also the most important criterion employed in many of the various classifications of party systems. Two-party systems, for example, are referred to as such not because there only two parties present themselves to the voters—indeed, this is rarely if ever the case—but rather because only two parties matter when it comes to forming a government, be this in a presidential or a parliamentary system. In two-and-a-half or multiparty systems, by contrast, there are more than two parties that enjoy the potential access to executive office. Even within the more complex classification developed by Sartori, it is the competition for office that proves most important. Sartori's moderate pluralism, for example, involves competition between alternative coalition

governments, whereas polarized pluralism involves a patterns in which a center party or parties is more or less permanently in office, with one or more extreme parties being permanently excluded from government.

It follows from this that party systems might best be understood not only in terms of some all-embracing classification, within which the question of the numbers of parties in competition obviously plays an important role, but also in terms of contrasting patterns of government formation (Mair 1997, pp. 199–223). Three related criteria are important here. The first concerns the ways in which governments alternate with one another, where systems in which there is a regular process of wholesale alternation, in which incumbents are replaced wholly by former nonincumbents, may be separated from those in which alternation is only partially complete. Systems in which two alternative parties or coalitions alternate with one another (the USA, the UK, Fifth Republic France) may therefore be distinguished from those in which one or more parties leaves office, while another remains, albeit often with a new coalition partner (Belgium, the Netherlands). The second, relevant criterion here is familiarity, where systems in which government is always contested by the same parties or sets of parties may be contrasted with those in which patterns of government formation prove more innovative or promiscuous. In postwar Ireland, for example, voters had long become accustomed to facing a choice at election time between, on the one side, the powerful *Fianna Fáil* party, which always governed alone, or, on the other side, a coalition of all of the smaller parties. Once *Fianna Fáil* decided to opt for a coalition strategy, however, in 1989, government formation became more innovative, and the formerly familiar patterns broke down. The third criterion involves the degree of access to the government formation process, and the extent to which new parties can hope to win a place in the executive. New parties have always found it relatively easy to join innovative government coalitions in the Netherlands, for example. In the UK, by contrast, no party other than the Conservatives or Labour has gained access to government since 1945.

Putting these three criteria together enables party systems to be ranged along a notional continuum according to the degree to which the structure of competition is open or closed. At one extreme lie the wholly closed systems, such as the UK or the US, where alternation in government is always wholesale, where government formation processes are wholly familiar, and where new or third parties are always excluded. At the other extreme, it is difficult to speak of a party system at all: there is no discernible pattern in how governments alternate, the potential alternatives themselves are unfamiliar and may never have governed before, and access to office is, in principle, open to all. To travel from this latter extreme to the other is therefore to witness the progressive closure of

the structure of competition, which is simply another way of saying that systemness itself increases. Party systems as systems are strongest and are most institutionalized when the structure of competition is closed. They are weakest, and more or less nonexistent, when this structure is wholly open.

To understand party systems in this way, and hence to treat the systemness of a party system, or its degree of institutionalization, as a variable, also affords an insight into the question of the persistence and change of party systems. Strongly institutionalized party systems will inevitably enjoy a bias towards persistence, not least because the parties at the core of such systems will have a vested interest in maintaining the existing structure of competition. It is for this reason, for example, that Lipset and Rokkan (1967) could speak of the 'freezing' of west European party systems in the wake of full democratization in the 1920s. Less institutionalized systems, on the other hand, will prove more susceptible to change. This approach also affords an insight into the relationship between party systems and individual parties, for it is not just the individual parties that together create the party system, but also the party system that acts to reinforce the role and standing of the parties themselves.

Pastoralism in Anthropology

Pastoralism refers to a range of subsistence modes based on specialized herding of domestic animals on

free range, and culturally dominated by values associated with such an economic adaptation. Examples are the social formations based on small-stock oriented commercial meat production and long distance trading in the Middle East, on reindeer herding and hunting in the subarctic regions or on the subsistence-oriented cattle and small-stock herding in East Africa. A common synonym to 'pastoralist' is 'nomad.' Since adjustment to animal needs necessitates as well as makes possible a mobile adaptation, the whole pastoral household or parts of the labor force may be permanently or seasonally migrating. The extent of mobility is however in fact highly variable, and dependence on herds a more significant factor than mobility in itself, so that the term pastoralism is preferable. It is useful to consider as pastoralists mainly people for which livestock have a double function as both a means for the production of utilities such as foodstuff, wool, or skins, and as a form of capital with the potential of growth, primarily used for such production (Barth 1964, p. 70). This contrasts them to 'agro-pastoralists' using their herds primarily as an agricultural capital, for example, traditional cultivators in East Africa who invest in cattle to expand the household's agricultural labor pool through bride-wealth and polygyny. Pastoralism is labor-intensive in the sense of requiring a large number of hands for different tasks, and thus also commonly contrasted with, for example, ranching, where fencing makes a much less extensive use of labor possible.

Within the limits of such definitions, 'pastoralism' refers to a wide range of very different situations, regions, and times. Milk-based economies built on cattle/small stock in East Africa and on camels/flocks in the Horn of Africa date 2,000–3,000 years back. Pastoralists exploiting arid regions use species diversification as a risk reducing strategy: different species are subject to different hazards, have supplementary production patterns and require different labor. Contemporary East African pastoralism is based on an emphasis on cow or camel milk production for subsistence purposes, supplemented with small stock rearing to produce milk or meat for market sale or household needs. In the present situation there is often a change towards commercial production of small stock for the meat market, although authorities often encourage the sale of immature cattle to the livestock industry. The basic division of labor in such societies is that young men take care of mobile adult cattle and camels out of lactation, allowing them to profit from valuable but distant pastures. Women, children, and elderly men look after lactating dams and cows, calves, and small stock. These are often managed in a less mobile fashion if conditions allow. In East African cattle cultures, a careful attitude about the reproductive potential of the herd is a prime moral value that reflects on the fundamental worth of the pastoralist as a human being and as a member of the community. Reproductive capital could traditionally

only be disposed of in socially and ritually meaningful contexts such as gift-giving, bride-wealth, or stock friendships. The typical form of social organization among such pastoralists is a confederation of intermarrying clans, led by the property-holding senior men and identifying themselves as having a common ethnicity.

Middle Eastern pastoralism has an emphasis on sheep and goat rearing for the purpose of producing milk and/or meat for domestic consumption or sale. Such pastoralism has existed in the Middle East, around the Mediterranean and in Eastern and Northern Africa for 3,000 to 4,000 years, and is today considered to have developed there as a supplement to horticulture. In the millennium before Christ, camel-saddling technology had developed enough to enable pastoral groups to involve themselves in long-distance caravaneering as well as in extensive camel-back raiding. This brought the breeding of transport and riding animals into the herding operation, and above all involved the desert dwellers in important political and economic relations with sedentary riverine or oasis polities. The spread of Islam reflected the need to find a religious basis of trust when trading out of reach of tight jural or political control. Most shepherding communities of the Middle East are today Muslims, although religious restrictions are often less tight than in urban areas. Small stock rearing provided a subsistence basis for desert or mountain-based family members who did not take part in caravaneering, which was mainly a task for select males. An interesting difference exists between Saudi Arabia and North Africa on one hand and Somalia on the other, in that Somali pastoralists exploit the camel primarily as a milk animal and do not ride it while camel milk is less important where the animal is ridden.

In central Asia other combinations of livestock have enabled other matches of raiding, trade and subsistence dairy production, such as, for example, the traditional salt trade in the Himalayas where yak and sheep are used both for transport and dairy production. Mongolian pastoralism places the strongest emphasis on horses and sheep. Although there are a number of good studies on these communities (e.g., Humphreys and Sneath 1999), they have attracted less contemporary anthropological attention than have East African or Middle Eastern pastoralists. Due to the legacy of the Golden Horde they have instead appealed to the interest of cultural historians.

Reindeer-based pastoralism in the subarctic tundra is the only contemporary form of pastoralism based on specialization in one species. It is considered the most recently developed form of specialized pastoralism and thought to have developed out of hunting only during the last millennium. Herders follow the natural movements of reindeer herds whose primary use is the production of meat. Contemporary Sami herding in Scandinavia is market-oriented, motorized, and generally a large scale operation (Ingold 1980).

Evolutionary anthropologists and philosophers of the eighteenth and nineteenth century concerned themselves with pastoralism because it was assumed to be a transitional stage between hunting and agriculture. Engels, inspired by Morgan, took a particular interest in it, because he saw livestock holdings as the origin both of private property and of male domination. Serious field research among pastoral people was undertaken only in the 1940s and 1950s when monographs on groups such as the Nuer, Dinka, and Somali came to play a decisive role in the development of British structural-functional theorizing about patrilineal descent systems. Within other scholarly traditions, attempts were made to find suitable ways of systematically classifying pastoral economies into subtypes (full nomads, seminomads, etc.) often based on the relative time spent on the move or relative dependence on agriculture. These classificatory systems for a long time dominated what was written on pastoralism but were not theoretically productive.

Substantial progress in the study of pastoralism can be traced to three different but intertwined strands of research that were prominent in the late 1960s and throughout the 1970s. One followed American traditions of cultural ecology and focussed on adaptation. The second was prominent in France and pursued Marxist analyses of modes of production. The third was inspired by Barth's theories of economic action. The conjunction of these interests, followed up by participatory fieldwork, led to a boost in understanding the technical aspects of pastoralism, the complex set of resources required, and the problems of continuity involved in sustaining herd capital over time in arid regions characterized by unpredictable climatic conditions.

As noted, pastoral production involves both a production of utilities and a continuous reproduction of livestock capital. Paine (1971) made a useful distinction between herding and husbandry. The first referred to the care for the wellbeing and growth of animals as such and husbandry is the management of the herd in its totality. The latter takes place through investments, acquisitions, or culling and sales and involves the herd owner in socially highly significant transactions that establish relations of friendship, affinity, economic insurance, spread of risks, and political alliance that are necessary for a socially and economically secure existence as a pastoralist. This implies a long-term scheming which has a very different time perspective from making herding decisions. The latter are made on a daily *ad hoc* basis, taking into consideration the latest information about the nutrition, health, and productive status of the animals as well as the quality and quantity of fodder and water available in accessible pastures, the presence of predators and human enemies, and the immediate availability of labor.

Pastoral economic power has several facets: control over the animals as food producers and as objects of

exchange, and control over the growth potential of one's livestock herd. This makes possible multifaceted property concepts. Animal wealth can be redivided, redistributed, and reorganized in a number of ways, creating diversity in rules and practices of inheritance and other forms of transgenerational property devolution. Senior men often strive to control the labor of younger men by retaining ultimate control of the latter's future herds and by summoning ritual prerogatives such as blessing power among the East African pastoralists or closeness to ancestral spirit owners of the land among the Mongols.

Property rights to grazing and water demonstrate a wide span of variation, depending on the territorial regularities of movement. East African pastoralists exploit land that can be seen as either government property or divine property, as open access or as a commons held by the ethnic group. Transhumant Middle Eastern pastoralists may have very definitive rights to seasonal routes. The Beja clans of Sudan claim tracts of land primarily for defining the political privilege of host-ship. Such differences in land right patterns reflect the degree of predictability in location and extent of seasonal rainfall or river flooding as well as the farming cycles of agricultural neighbors and concomitant fluctuations of markets. Seasonal regularity and predictability structure the possibilities for control of land, grazing, and political power. Pastoralism does not represent any single way of organizing relations of production (cf. Bonte 1981, p. 30). There is a great divergence for example between the quasi-feudal Khirgiz of Afghanistan on the one hand and the loosely organized Turkana of Kenya on the other. The Khirgiz khan distributes stock-loans to thousands of clients while among the Turkana each household strives for its own independence through cattle which are either owned by themselves or borrowed on a more egalitarian basis between stock allies. The issue of the forms of inequality that could be found within pastoral societies and the mechanisms often maintaining a relative degree of egalitarianism has interested many of the researchers referred to. If livestock rearing is considered *per se*, there are many practical problems that are common to pastoralists in different parts of the world, yet the ecological niches they occupy also allow for substantial variation. However, the insufficiency of ecological determinism for understanding pastoral cultures and social conditions has become apparent particularly in relation to such questions of equality and inequality.

Over time, anthropologists looking at pastoralism have come to place more emphasis on the various ways in which pastoral communities were integrated in larger regional economic and political systems, and on the interlinkages between pastoral production and other economic activities. An observer who considers the activities of a pastoral group in a particular place and time is easily misled to disregard the variation that a long-term perspective reveals. Later research has

emphasized that pastoralism is not necessarily a static, 'pure' adaptation, but rather a stage in a flexible series of adaptations to irregular climatic circumstances. It has only existed as a pure subsistence form under particular historical conditions. What is more typical for pastoralists than a monodimensional dependence on one type of resource is flexibility in combining different resources. To survive as pastoralists in the long term, livestock-rearers have had to integrate supplementary pursuits such as venture farming, small scale-irrigation, famine-year hunting, or trade. With a longer-term perspective on some of the ethnic groups of East Africa, a gradual switch between dry-land agriculture, pastoralism, and hunting seems to be no rare occurrence. The apparent degree of specialization in and dependence on pastoralism is thus often spurious. Pastoralists whose work is dominated by care for animals still normally depend on getting parts of their diet from farm produce. Small-scale supplementary cultivation can be added to pastoralism in innumerable ways or these products can be secured from others through barter or cash trade, predation, tribute taking, or labor services. The large variation in possible solutions to this problem in itself precludes ecological determinism as a fruitful point of departure for understanding social organization. Processes of stratification and equalization within the pastoral communities can only be understood when these modes of articulation with surrounding structures are taken into account. Today, an essential issue is to what extent a pastoral group in their combination of assets have access to cash or other resources that can act as a security independent of fluctuations in herd health or climate.

In the 1970s and 1980s, the famines among African pastoralists hit by drought coincided with the international breakthrough of environmentalist discourse. Desertification became a catchy symbol of how humanity was overexploiting its brittle resource base. Hardin (1968) presented his theory of 'the tragedy of the commons,' using as an illuminating but fictive illustration a herd-owner's use of pastures. Maximizing his individual gain, the herd-owner was thought not to pay attention to the collective good. In the end all herd-owners would accordingly lose from their own faulty strategy. Hardin's theory was picked up by policy-makers dealing with pastoral development in East Africa. During the 1980s and 1990s a concern for how policies informed by Hardin's theory affect the situation of pastoralists has turned opposition to Hardin's model into a major inspiration for anthropological research. The debate has centered on the degree to which human-induced desertification is taking place. Are pastoralists to be blamed for overgrazing or to be seen essentially as conservationists? The anthropological critique of Hardin and of evolutionary ecologists is often intermixed with an ecological-technical critique, considering the long term effect of pastoral practices on species diversification

and erosion, emphasizing the resilience of desert vegetation, the relative local impact of global climatic change, and inadequacies in models relating grazing pressure to the subsequent availability of good fodder. More anthropological argumentation emphasizes the necessity to distinguish between the knowledge, values and considerations actually expressed among herdspeople and the effects of their herding practices. A methodological issue, dividing social scientists and evolutionary ecologists, is whether 'self-interest' can be analyzed as a causal variable independent of how the actor interprets his own strategies and choices. Pastoral anthropologists question the relevance of the fictive decision-making situations postulated by model-builders like Hardin to the choices real herd-owners have to make. Pastoral economies are based on constant recombination of the available resources of livestock capital and food, and in order to match productive resources and consumption needs as efficiently as possible. This makes the household a debatable unit of analysis. Anthropologists also emphasize the existence of collective institutions and norms which serve a conservationist function, and argue that external observers often think in terms of quantity and tend to neglect quality issues that pastoralists deem entirely important in relation to the composition of a herd and to fodder, minerals, and water. Neither is the parallel and intertwined rationalities of herding and husbandry appreciated. Caring for continuity involves more than a concern for water and fodder: it requires concern for securing access to territory, to docile, fertile, and reproductive stock and to reliable and knowledgeable labor—all critical resources that cannot be taken for granted but have to be continuously ensured.

While the 1970s gave fresh insights into pastoralism at a generalizable level, the field has been relatively stagnant in the 1980s and 1990s, except for the argumentation in defense against pastoralists blamed for desertification. Plentiful documentation has however been secured of threats to the viability of pastoral subsistence. Official worries over the situation of pastoral nomads are concerned with land degradation, but evidence particularly from East Africa points to problems associated with the extent of accessible pastures rather than their quality. Contemporary pastoralists suffer a successive limitation of critical grazing or water assets through the expansion of towns and of small-holder farming and large-scale mechanized agriculture, through irrigation schemes and game reserves and more brutally, through the expansion of zones of war or insecurity.

Technological changes such as motorized surveillance and transport of herds, easy fencing, mechanical watering, or stationary foddering create forms of management more profitable but less efficient in terms of providing work and food for a large number of people. A concentration of stock ownership takes place parallel to a transition to more intensive small

stock rearing at the expense of cattle or camel herding, something which has been suggested to have negative ecological consequences in the long run. The diversion of farm products once provided by cultivating neighbors into other more competitive markets is another serious problem to modern pastoralists.

Patient Adherence to Health Care Regimens

1. Overview

Research conducted since the 1970s has demonstrated that, on average, about 40 percent (and in some cases as many as 90 percent) of patients fail to adhere to the

recommendations they have received from their physicians for prevention or treatment of acute or chronic conditions. This is a serious problem known in the medical literature both as 'patient nonadherence' and 'patient noncompliance.' The broadest definition of the terms is that a patient fails to manifest behaviorally the health professional's (usually physician's) intended treatment regimen. It consists of such actions as the patient failing to take antibiotics correctly, forgetting or refusing to take hypertension medication, forgoing important health habits, and persisting in a dangerous and unhealthy lifestyle. As a result of failure to adhere, many patients become more and more seriously ill, they develop infections that are resistant to treatment, physicians alter patients' treatments based on misunderstanding of its initial effects, physicians are misled about the correct diagnosis, and the time and money spent on the medical visit is wasted (for reviews see DiMatteo and DiNicola 1982, Meichenbaum and Turk 1987, Myers and Midence 1998, Shumaker et al. 1998).

2. The Conceptual and Clinical Importance of Adherence

The issue of patient adherence has both conceptual and clinical implications. In the realm of clinical medicine, the decade of the 1990s brought amazing advances in the treatment of both acute and chronic illnesses, vastly improving quality of life for those suffering from them. Even HIV has promising treatments in the form of highly active antiretroviral therapies. Attempts at managing medical costs have enhanced the focus on preventive services. There are concerns, however, about the re-emergence of infectious diseases, as some bacterial infections that were once straightforwardly treated with antibiotics remain resistant even to the most powerful antibiotics. In HIV, viral resistance to the protease inhibitors has emerged just when control of the disease seemed possible. It is now recognized that noncompliance may be one of the major causes of these reductions in the efficacy of medical treatments, the proliferation of drug resistance, and the waste of billions of health care dollars.

In the conceptual realm, the achievement of patient adherence involves the phenomenon of social influence. A health professional essentially tries to influence a patient to change their behavior. Because medical care is delivered through the interpersonal interaction between health professional and patient, it may be best understood as a social psychological phenomenon. Thus, relevant are issues of communication, trust, persuasion, social normative influence, social reinforcement, and social support.

The understanding of compliance/adherence is complicated further by the philosophical issue of patient self-determination, often examined in detail in writings

on medical ethics. It is also affected by issues of information processing, understanding, and retrieval, and the sometime interaction of these issues with that of self-determination. For example, a patient might be noncompliant simply because they never understood the regimen in the first place due to anxiety in the presence of the physician. This patient would follow the regimen had they understood it. Another patient might conveniently 'forget' to follow the treatment in an effort to exert a certain amount of self-determination. Yet another patient might choose 'alternative' medicine therapies, instead of medically recommended ones, because the former may be both easier to understand and provide the patient with a greater sense of control. Finally, by failing to adhere, another patient might be consciously or unconsciously trying to commit suicide, either through clear-headed choice or because of severe depression.

3. Controversy Over the Term Reflects a Philosophical Issue

Historically, the behavior of following a physician's recommendations has been termed 'compliance,' and reviewing the literature from indexed databases, particularly before 1990, has required the use of this term. Some writers (see Haug and Lavin 1983) have argued that the term compliance implies coercion, emphasizing paternalistic control on the part of the physician. Many writers have more recently used the term adherence,' which seems to imply that the patient, in a more self-determining manner, 'sticks to' the regimen if they choose to do so. Still others have argued that the appropriate term is 'cooperation,' which patient and physician may or may not achieve, depending upon their willingness and ability to negotiate effectively with one another. Studies do show that patient adherence is highly dependent upon patient involvement in medical choices and patient commitment to treatment decisions, and so cooperation, as well as participation, negotiation, and partnership are essential. The use of all these terms creates, of course, an indexing nightmare, and so the terms 'adherence' and 'compliance' have remained dominant. Although not always referred to as such in indexing, research on aspects of patient self-determination suggests it to be an essential element in adherence and health behavior change.

Whatever it is to be called, the phenomenon of a patient following through with a health professional's treatment recommendations is not a simple achievement. Given the potential for difficulties at several steps—from the physician conveying information about the regimen, to the patient remembering what was conveyed, to the patient wanting to carry out the behavior, to actually overcoming all the difficulties of doing so—one can easily understand why non-compliance rates are very high.

4. Theories Guiding the Research

Various theoretical models have driven, in some fashion or another, the research on patient adherence (see *Health Behavior: Psychosocial Theories*). They include social cognition approaches that emphasize the patient's thoughts and beliefs as primary influences on adherence behavior. Many theories use a value-expectancy paradigm, in which behavior in response to a threat to health arises from expectations that the action will be self-protective. The Health Belief Model is one such approach, and it emphasizes thoughts regarding risks and benefits of the recommended course of action (Janz and Becker 1984). The Theory of Reasoned Action takes account of beliefs and of social influences, and emphasizes the role of intentions and their tenuous connection to action. The Theory of Planned Behavior adds to this a consideration of perceived behavioral control and perceived barriers to action (Ajzen 1985). There are also attribution theories, in which people are posited to be concerned with explaining the causes of events in terms of their locus of control (internal vs. external), stability, and universality (Wallston et al. 1994).

Some models are based on efficacy beliefs regarding both the ability of the self to carry out the target behavior, and of the action to affect the intended outcome (see *Self-efficacy and Health*). There are likely to be limitations to linear rationality in decision making, and recent modifications of the social cognition approach have tried to take these limitations into account. One of these modifications is the Trans-theoretical, or Stages of Change, Model that proposes that adherence occurs through progressive, nonlinear stages or steps of behavior modification and maintenance (Prochaska and DiClemente 1983). Finally, self-regulatory models view the patient as an active problem solver who strives to achieve a health goal by identifying the health threat, developing and implementing an action plan or coping procedure to deal with the threat, and appraising the outcome of the action (Leventhal and Cameron 1987) (see *Health: Self-regulation*).

No single model is universally valid, or even helpful, in the study of adherence, particularly because the complexity of treatment regimens varies widely from one disease to another. An approach that organizes the research on adherence in terms of a purely biomedical model tends to classify and analyze adherence studies by disease conditions and finds some interesting trends and patterns that might provide clinically relevant insights for the care of specific disease conditions. The difficulty with this approach, however, has been that similarities in psychosocial phenomena across disease conditions are not apparent, and findings that could be applicable to all patients may remain undiscovered. Focusing solely on psychosocial issues, without regard to the uniqueness of disease conditions, may introduce too much variation

into the analysis, making trends difficult to determine. A combined 'biopsychosocial' approach, on the other hand, allows for the analysis of psychosocial factors in the context of the specifics of various diseases and treatment conditions.

5. Limitations in the Literature

Since 1968, there have been over 9,000 papers published about patient adherence (or its alternate name, patient compliance), with a ratio of more than two reviews/opinion pieces to one empirical article (Trostle 1997). Most of the empirical publications have examined only one or two predictors of adherence, either in an observational study or in an intervention to improve adherence/compliance. These studies have demonstrated, not surprisingly, that doing something to help patients comply is better than doing nothing, and that compliance can usually be found to correlate with something about the patient (e.g., motivation), the regimen (e.g., its complexity), or the interaction between patient and health professional (e.g., communication). Studies that have examined several elements of this very complex phenomenon are, on the other hand, rather few and far between. Most chronic illnesses, where adherence is very difficult (e.g., adolescent diabetes), are quite demanding psychologically and behaviorally. Designing and maintaining an effective treatment package requires understanding the entire picture of compliance, from communication of the regimen to its implementation. Unless the phenomenon is fully understood in all its complexity, it is impossible to know when, where, and how it might be best to intervene to help patients to adhere.

6. A Multidimensional Approach to Noncompliance

In examining how difficult and complex adherence to a treatment regimen might be, it is useful to consider a clinical example. Imagine a 48-year old, moderately overweight, borderline hypertensive, male patient who has been told by his physician that he should begin and maintain a program of regular exercise. The goals of this exercise are to reduce his weight, to lower his blood pressure, and improve his level of HDL cholesterol. He understands quite well what he is being asked to do, and he believes that exercise is important and worth the trouble and time it takes. His family and friends agree that the regimen is valuable, and encourage him to follow it. His family members remind and encourage him daily, and have even invested in a treadmill for him to use each evening. In this case, as in general, exercise compliance demands a multidimensional, multifactorial approach because changing the sedentary habits of a lifetime can be very

difficult and often meet with failure. Even among rather seriously at-risk patients, such as who have cardiovascular disease, diabetes, or a previous myocardial infarction, there is a 30–70 percent dropout rate from exercise. In such situations, as with our example patient here, people may have very positive attitudes toward exercise, and even strong networks of social support, but still fail. Maintenance of these very complex behavioral changes over a long period of time requires very careful attention to many factors.

7. Factors That Affect Patient Adherence

As noted above, there tends to be something of a disjuncture between the theoretical models of adherence, most of which are multidimensional, and the empirical findings, which are primarily unidimensional. Nevertheless, the empirical studies tell us some important facts about adherence that are useful both clinically and in terms of how they contribute, albeit in a limited fashion, to the theoretical models. Patient demographics, for example, are thought by many clinicians to be the best predictors of patient adherence. Physicians tend to use easily available information from the clinical encounter to steer their attention to those they believe to be at highest risk for nonadherence. Despite physician beliefs, however, patient age and gender seem to have very little relationship to adherence (except, perhaps, that adolescents tend to have more problems adhering than other age groups). Further, although lower income patients and those with more limited education have somewhat lower levels of adherence than more affluent and educated patients, the effect is quite small, and not nearly as important as that of other variables that can be altered.

Psychological variables, such as attributions, locus of control, and beliefs, while important in the models noted above, have not shown consistent effects on adherence. For example, believing that a disease is severe may in some cases prompt a person to take consistent action to avoid or treat that disease, and in other cases bring about denial and reckless abandonment of the regimen. On the other hand, the effect of another psychological variable—depression—on adherence is potentially noteworthy and should be examined further. Depression may bring about hopelessness and isolation, two phenomena that reduce adherence considerably; but it may be entirely treatable (see *Depression, Hopelessness, Optimism, and Health*).

Adherence has been found consistently to be dependent on the patient's social support system and family/marital environment. Further, a regimen's complexity and adverse effects must not be overlooked by physicians when making a medical recommendation; much research has found that nonadher-

ence is related to long-term regimens with complex and confusing dosages and scheduling. Health professional-patient communication seems to affect adherence as well. Because of limitations in communication during the medical visit, patients may misunderstand what they are to do, and the anxiety of the situation tends to interfere with recall at a later time. The sensitivity and empathy in physician-patient communication often matters as well, because patients tend to be more likely to try to adhere to recommendations given by health professionals that they like and trust. Patients' health beliefs and attitudes, often influenced by their cultural patterns and expectations, may conflict with the regimen, making adherence difficult, and practical barriers, such as side effects and lack of necessary resources, may interfere with the regimen (see *Health and Illness: Mental Representations in Different Cultures*). Finally, studies show that physicians typically do not know whether or not their patients are adherent. They overestimate the degree to which their patients follow their directives, and are typically unable to identify which patients are having adherence problems. Yet, the accurate assessment of adherence is essential because achievement of adherence has been shown to make an important difference in patient outcomes and patient health status.

8. Research Challenges

A major research challenge in the field of adherence involves its measurement. It seems obvious that one good way to measure adherence would be simply to ask the patient. In fact, most adherence research and clinical practices have relied upon the technique of self-report, although such an approach may be biased by self-presentation and by patients' fears of reprimand by the physician. Reports of spouses or other health professionals can be useful, but these reports may vary in accuracy depending upon the opportunity to observe the patient's daily activities. Techniques such as pill counts, patient behavioral diaries, and electronic recording devices have their own drawbacks, including patient manipulation toward the goal of concealing nonadherence. Tests, such as urine or blood assay, may be useful for medication, but tend to reflect only its recent consumption. Physician reports and chart entries are unreliable and are often based on unclear criteria. Because there is no 'gold standard,' convergence of the findings of research is more difficult to achieve. Necessary to the field is the development and implementation of methods for building therapeutic trust so that patients can be forthcoming and frank about their difficulties in following treatment suggestions, and both measurement and adherence itself can be improved (Hays and DiMatteo 1987).

A second issue of concern is that most reviews of adherence have been qualitative. Many writers, in-

cluding this author, have described extensively the factors that influence patient adherence, ranging from the importance of physicians' communication skills to how simple or complex the regimen should be. Although these reviews have attempted to be exhaustive, their conclusions have been biased by several factors including limited sampling of the population of empirical studies, and entrenched, established social psychological (or other) models of behavior guiding their organization. Further, when studies are listed and the effects of different variables on adherence are described, there are invariably conflicting results that cannot be resolved qualitatively. When there is a huge amount of research available, such as on adherence, it is possible to review only a sampling of it, resulting in further bias unless that sampling is random. One good quantitative assessment of a complete set of empirical studies, however, is worth many expert opinions and reviews. Fully understanding all of the complex elements of adherence involves painstakingly organizing, reviewing, and quantitatively summarizing the entire abundant literature on each variable related to adherence employing the research technique of meta-analysis. Nothing short of this will provide the clear answers that are necessary. Such an approach would allow for a better overall understanding of the complex relationships between adherence and characteristics of patients, their lives, their diseases, their regimens, the therapeutic relationship, and the context of medical care delivery.

Finally, conceptual and empirical work is necessary to remedy the common confusion of adherence behaviors with adherence outcomes. A patient might carry out flawlessly every behavioral requirement of care, but the outcome may remain disappointing. Research must pay scrupulous attention to the accurate assessment of behavior, and recognize that physiological measures of outcome should never serve as proxies for adherence. The independent effect of adherence on achieving health outcomes, health status, functional status, psychological and social functioning, and all aspects of health related quality of life needs to be examined (see *Quality of Life: Assessment in Health Settings*).

9. Conclusion

As noted above, despite the complexity and multidimensionality of theoretical models of adherence, nearly all of the research has examined individual factors that correlate with adherence. These empirical investigations have provided some useful answers about adherence, but the theory that could be helpful in guiding our research questions remains disconnected from it. Fully understanding adherence has remained an elusive goal because reviews of the literature have been equivocal. Clear answers are

necessary, however, as some of these questions have strong clinical and policy implications.

This review of the literature has attempted to view it as a whole, to the extent that a qualitative approach can do so, and to point out its strengths, limitations, and promising trends. At this point in time, there are many reviews, and not enough well designed, well executed, multidimensional, longitudinal empirical studies of adherence. Now that we have a compilation of studies in the univariate realm, it is necessary to work toward multifactorial explanatory approaches to adherence. These models need to examine simultaneously the effect of social, psychological, and biological variables on adherence, and to examine their unique interactional effects. Only then will a full and clear picture of this complicated phenomenon emerge.

Patriotism

‘Patriotism’ is about political allegiance (and, of course, loyalty), commitment, and dedication. In briefest compass, it means love of one’s country or nation and is one of the oldest political virtues. It is rather more emotional than rational in its appeal and demands recognition of what is presumptively a pre-existing duty to that political order or state. One of the best exemplars of patriotism is Stephen Decatur’s well-known toast in 1816:

‘Our Country! In her intercourse with foreign nations may she always be in the right, but our country, right or wrong.’

To which John Quincy Adams replied:

‘My toast would be, may our country always be successful, but whether successful or otherwise, always right.’

Patriotism depends upon an often unarticulated principle that is the political counterpart to the ‘blood is thicker than water’ adage, which reminds people that they should prefer their families before all others. Patriotism is a natural consequence of political membership or citizenship, and it is not clear where—other than membership itself—the duties of patriotism originate or what justifies them other than that membership, for patriotism is not voluntarily assumed as general political obligations are presumed to be. To deny or renounce patriotism or to act contrary to what its proponents deem appropriate is to be disloyal.

There is a Burkean quality to patriotism, both because it projects an almost organic, trans-historical unity among the member of a state, nation, or people such that each individual is inseparable from the past and because it looks to that past and to the achievements of one’s political ancestors rather than to one’s own accomplishments as sources of pride and holds up those achievements as standards by which the successes of the present are to be measured. In this respect, patriotism can be nurturing as well as oppressive, for it defines and constitutes the political member and, in the process, restricts that member’s range of permissible options.

Patriotism is rarely invoked but is in times of stress or trouble. The call for patriots or acts of patriotism is issued when a sacrifice for the presumed good of the people or their state is needed, usually because that good is perceived to be in jeopardy or under attack. In the period since World War II, those attacks have most often been alleged to come from inside a system, from people who in an earlier day would have been labeled ‘traitors’ but are now more conventionally called ‘disloyal’ and even ‘outsiders.’ During World War II, in Europe, according to the *OED*, a patriot was a ‘loyal inhabitant of a country overrun by the enemy, especially a member of a resistance movement.’

But for nearly 150 years prior to that, also according to the *OED*, because the mantle of the patriot had been assumed by persons who were deemed not entitled to it, the term itself was somewhat discredited. Dr Johnson, amplifying his dictum that ‘patriotism is the last refuge of a scoundrel,’ noted that the word was used ‘ironically for a factious disturber of the government.’

Etymologically, ‘patriotism’ springs from the Greek, via Latin, for father and father land, (πατριώτης, from πάτριος of one’s fathers, πατρίς, one’s fatherland; late Latin *patriota*, fellow-countryman [*OED*]), suggesting political membership based on kinship as well as an implicit reliance on family-like bonds to hold a state together. And in the Latinate tongues of Europe, various cognates of *patria* mean ‘fatherland’ or native country. Native too, as well as nation to which it is conceptually and etymologically related, suggests kinship, but these resonances have long since been buried by linguistic evolution. Their value today is primarily as reminders of the emergence of the political order from tribal, familial associations. ‘Fatherland’ is more obviously familial, and its roots are Germanic rather than Latinate. (Interestingly, German has adopted the Latinate forms *der Patriot* and *der Patriotismus* even though it has its own words, *der Vaterlandsfreund*, literally, *friend of the fatherland*, and *die Vaterlandliebe*, *love of the fatherland*.) But patriotism has never had this familial resonance in English, which explains why the term has an air of contentiousness and alarm about it when invoked in English and why its English-speaking history has been checkered. In that largely individualist and voluntarist world, political duty, at least since the seventeenth century, has been viewed as a consequence of intentional commitment and a subject for reason and judgment. In those terms, patriotism has often seemed like an alien concept.

Patriotism is more at home in the conceptual world of republicanism. The republican tradition has always looked upon the state as a closely-knit and relatively homogenous association. Patriotism calls upon the members of this association, when appropriate, to put aside whatever divides them and to rally in support of what they share, a practice that is integral to the communitarian predilections of republican society but stands in need of justification from the perspective of individualism. The call for patriotism—for people to be patriotic, for those who are already patriotic to come forth in the spirit of the *patria*—is an appeal to the emotions, no less than love in its ordinary sense is an invocation of affect rather than reason. And like the affections that bind friends and family members, patriotism works by reminding those at whom it is directed of their ties and of their non-voluntary relationships to other people. Thomas Paine’s ‘sunshine patriot’ is a play on the better known ‘fair weather friend,’ both demeaning of the self-styled supporter who is unwilling to be inconvenienced.

Patriotism is rooted in emotions rather than reason and has to do with feelings of commitment and loyalty to one's nation or state and pride in its history and accomplishments. While it is not necessarily irrational or even unthinking, patriotism does pose as the supreme call on one's commitments, the one that trumps or overrides others with which it may compete.

With the revival of classical republican thinking in English-language political discourse, toward the latter part of the twentieth century, patriotism made an almost grudging return. Republicanism values 'community' and 'civic virtue' with which it seeks to supplant individualism, self-willed obligation, and institutional legitimacy. Further sources of the renewed appeal to patriotism are the collapse of Eastern European communism and the ensuing struggles for national identity and 'liberation.' These linked patriotism to ethnic and religious nationalism (which are akin to those flourishing in Northern Ireland, the Middle East, and on the Indian Subcontinent). Even earlier, the worker and student protest movements of the 1960s and 1970s—especially in France, Germany, the UK, and the USA—and the American civil rights movement were all surrounded by claims of 'disloyalty,' and illegitimacy, which resulted in quests for the proper bearers of the mantle of patriotism. Finally, in the USA, the period of the Cold War was marked by zealous attacks on disloyal 'communist sympathizers,' often in the name of patriotism.

In the West, contemporary proponents of patriotism attempt to harmonize it with the Enlightenment value of 'cosmopolitanism' and struggle to separate it from the virulent nationalism with which it is too easily associated and which it often resembles. These efforts seem destined to fail, for patriotism is particularistic, not universal. It tells people that what they have in common is what deeply and importantly unites them and makes them a nation or a 'people.' This unity overrides their differences. There is, in consequence, a tendency to homogenize those differences into a political blandness that could render society uninteresting and potentially stagnant. Far worse than that, however, patriotism in this homogenizing form prepares the way for the insistence that a greater, underlying good assigns places in the social order. Because of the fundamental sameness of all members, there are no remediations for deprivations. Those who are not sufficiently 'the same' are outsiders who can and should be excluded.

The modern state at the beginning of the twenty-first century is increasingly complex and heterogeneous in ways that traditional patriotism cannot comprehend. Moreover, individual states cannot reject that heterogeneity and continue to exist in a world of international political and economic exchange. States today inevitably function in a world that is at odds with their claims of internal uniformity. That internal coherence—where it is more of an ideal than a fact—often leads to oppression. There are few states

that do not have internal 'minority' peoples who dissent or are excluded from the presumed consensus that undergirds patriotism. While this is not to say that internal political loyalty and cultural and social diversity are incompatible, the responses of the advocates of patriotism to the circumstances that call forth their pleas are antagonistic to cultural variety. One of the hallmarks of modern politics is tolerance and forbearance by states and their members. But tolerance, by its nature, undermines both the spirit and the practice of patriotism. It is far easier—and in many respects more desirable—to give loyalty to those who are regarded as like one's self, which is among the principal reasons that the habits of obedience that patriotism fosters and on which it depends are usually rooted in the family. To bestow that same deference on an 'alien' authority or on one that appears to uphold a different set of values from one's own is often difficult and can require acts of will and judgment that are antithetical to the non-rational, emotional bases of patriotism.

At the same time, however, so long as there are territorial nations, there will be reasons for inculcating loyalty to them; nations necessarily require their members to make sacrifices from time to time, and it is certainly preferable that these sacrifices—these fulfillments of civic duties and responsibilities—be made willingly if not voluntarily and in the belief that they are justified. Individual members must have grounds for accepting the propriety of actions undertaken by and/or in the names of their states; they must feel some dedication and loyalty to their states. The inculcation of those feelings through the process generally known as 'civic education' must be done in ways that preserve the forbearance that toleration requires and do not give rise to the exclusionary and destructively ugly nationalism that often has patriotism as its partner.

Patron–Client Relationships, Anthropology of

Patron–client relations (PCR) involve asymmetric but mutually beneficial, open-ended transactions based on the differential control by individuals or groups over the access and flow of resources in stratified societies. Patrons provide selective access to resources they control, or place themselves or the clients in positions from which they can divert resources in their favor. In exchange, the clients are supposed to provide material and human resources, including their gratitude and loyalty, while boosting the patron's prestige and reputation. The study of PCR has revealed the persisting presence of interpersonal hierarchy in contemporary societies, contributing to the reevaluation of paradigms in social science. Debates continue about their institutional viability and significance in late modernity.

1. Terminology

The terms used originated in ancient Republican Rome, where relationships of *patrocinium* and *clientelae* proliferated during the Republic and into the Empire (later on, they were subsumed under what historians of late medieval times called *bastard feudalism*). These terms found their way into the vernaculars of Mediterranean and Latin American societies. Other terms are used for PCR elsewhere.

2. Background

Whereas in antiquity, PCR formed part of the normative framework of society and could hardly be thought as conflicting with legal institutions and the social ethos, in modern societies PCR are built around such a conflict. While in principle and by law the clients have access to power centers and the ability to convert resources autonomously, this potential is neutralized by the patrons' control over scarce re-

sources, be they land, water sources, employment, loans, schooling opportunities, medical services, public security, or infrastructure. PCR may be rooted in the search for protection, in bureaucrats' providing preferential access to petitioners in return for future favors, in poor people sharing the social visibility of men or rank, while the latter use these links to consolidate their status. Union leaders, political activists, and government officials may use PCR to build a network of supporters, instrumental for gaining higher-level positions, office, and control of resources.

3. The Study of PCR

Expanding in the 1960s, it led (by the late 1970s and 1980s) to general and comparative analyses. In the 1990s in-depth studies renewed interest in PCR in polities under transition to market economy and democracy, re-evaluating some of the premises of earlier approaches, especially regarding the connection between PCR and underdevelopment. The growth of interest has been connected with the spread of research from anthropology to the other social sciences. From early dyadic emphases, research has increasingly revealed a complex range of PCR analyzed in terms of networks, factions and coalitions.

The study of PCR contributed to analytical shifts, as it deals with phenomena for which neither the group corporate model nor formal institutional models provide a satisfactory guide. In parallel, research revealed the complexities of studying PCR, owing to their informal character and to their cross-institutional insertion that requires interdisciplinary knowledge, bridging anthropology and sociology, political science, and economics.

4. A Logic of Social Exchange

Research has identified a specific logic of exchange and reciprocity beneath the wide gamut of PCR. Both the control of material and human resources and the character of trust play a crucial role in it. This logic has been defined in the literature as clientelism. A related term is patronage, used interchangeably at times and alluding to the support granted by the patron to his followers and *protégés*.

This logic implies:

Control of markets. Individuals and institutional actors are able to gather followings by dispensing selective access to valuable benefits and resources. They do so whether acting as patrons (in a strict sense), or through their influence as brokers with those who control the goods and services, or through a combination of both roles, in what has been called patron-brokerage.

Inequality and asymmetry structured though an idiom of reciprocity.

Particularism. A relationship shaped according to the particular traits of the partners rather than on the basis of entitlements or formal roles.

Favoritism. Many people are excluded from PCR or are related indirectly or intermittently. Where clientelism is highly valued, it generates ‘inflationary’ expectations, many of which are disappointed.

The simultaneous exchange of instrumental (e.g., economic and political) and ‘sociational’ or expressive resources and services (e.g., promises of loyalty). A package deal allowing for more than a restricted balanced or market exchange is built-in, identified as connected to generalized exchange. This determines expectations of entering more embracing attachments, often couched in terms of commitment, even though some PCR are very ambivalent in this respect.

PCR undermine group (i.e., class and strata) solidarity among both clients and patrons, especially among clients, and to exacerbate resentment and social antagonisms.

PCR are neither fully contractual nor legal. Most PCR are vulnerable to systemic pressures and are characterized by instability, perpetual contest and resource manipulation.

5. Exchange Strategies

The agent performing as client is not only expected to provide his patron with specific resources but must also accept the patron’s control over access to markets and public goods, and over his ability to convert resources fully. In parallel, the patron’s position is not as solid as it may seem, nor guaranteed. Never fully legitimized, it is vulnerable to attack by social forces committed to universalistic principles, by the competition of other patrons and brokers, potential and actual, and by social forces excluded from PCR. Owing to these constant threats, patrons are compelled to rely on their followers to solidify their position. The patron must also relinquish some short-term gains to project public claims and to bolster images of power and reputation. Sometimes this earns him/her the right to determine the basic rules of the social relationships. In return the client is protected from social or material insecurity, and is provided with goods, services and social advancement. Certain types of trust (focalized rather than generalized) are associated with such dynamics.

Complementary exchange strategies are built, which signal what Vincent Lemieux defined as a ‘double transformation.’ That is, an abdication of autonomy on the client’s part and a relaxation of hierarchical controls on the patron’s part, through which the client’s lack of power becomes dominated power and the latter’s lack of domination becomes dominating authority. These exchange strategies are not only affected by immediate, mostly technical considerations of power and instrumentality, but often encompass

mutual, relatively long-term, compromises based on commitments as the prerequisite for ongoing social relationships.

6. The Context of PCR

Unlike societies in which hereditary ascriptive principles predominate, full-fledged clientelism flourishes where markets are no longer controlled through primordial units and allow for an open flow of resources and opportunities for mobility. (This is what distinguishes clientelism from *feudalism*, as pointed out already by Max Weber in *Economy and Society* (1968, Vol. III, Chaps. 12–13) and later on by historians of Europe). This trend, however, goes hand in hand with a strong tendency toward unequal access to markets and sociopolitical spheres. As they affect distribution and redistribution, PCR remain subject to the dynamics of political economy. Marketing economies, accelerated urbanization and the expansion of the regulatory, extractive, or even sporadic mobilizing activities of central administrations affect PCR. Research has shown that the impact of world economic trends, fluctuations in the price of commodities, the complexity of international trade, banking, and aid—all these affect the pool of patronage resources available to states and other agencies, and influence patterns of control, distribution, and redistribution. Moreover, as these arrangements are not fully legitimized, they remain vulnerable to the challenge of countervailing social forces.

7. The Comparative Analysis of PCR

Until the early 1980s, it was dominated by the contrast between traditional dyadic patronage and modern party-directed clientelism, a distinction that derived from the dominant paradigm of modernization. With a clear-cut developmental emphasis, this approach focused on differences in organizational complexity, deriving other aspects from it in a functionalist manner.

Since the 1980s, comparative analysis has paid attention also to other aspects. First, the way agents configure their role. Second, the styles shaping the relationship, following what Robert Paine called a ‘generative transactional model of patronage.’ Third, symbolic aspects such as images, discourse and trust, so important for the development of PCR. Fourth, the distinction between PCR as institutional *addenda* and clientelism as a major institutional strategy in certain societies and periods. Finally, PCR’s institutional viability in processes of democratization and liberalization.

8. Debates on Institutional Viability

Researchers differ in assessing the institutional viability and significance of PCR in late modernity.

From one perspective, PCR neutralize the system of representation and entitlements, by placing ‘friends’ in strategic positions of power and control. Clienteles are depicted as inimical to the institutionalization of public accountability and contrary to a politics, open to generalization and participation, and to a discourse of rights. Other authors emphasize the pragmatics of social action, stressing that PCR are an important mechanism for obtaining transactional benefits, in resource allocation, and in providing local–regional–national mechanisms of articulation. While PCR run counter to universalistic standards, it is claimed they are sensitive to local sentiment, may solve existential problems, provide access for migrant populations, and serve political entrepreneurs. From this perspective, as long as clienteles maintain some balance of reciprocity, the participation in political and economic markets by the ‘capi-clientele’ (to borrow Mosca’s expression)—be he or she a broker, a patron or a patron-broker—constitutes a means for individuals in their entourage to influence public decisions. In this sense, some literature alludes to PCR as reconciling public and private authority and formal and informal rules of the game.

PCR are criticized, and opposed by social forces and coalitions wishing to curtail its presence alongside bureaucratic universalism and market rationality. In parallel, sectors benefiting from patronage may see it as a pragmatic avenue of controlled freedom, useful for advancing in competitive social, economic, and political domains. This duality reflects a major tension of modern democracies, which are built on citizenship and political equality but leave the economic domain open to inequalities.

This explains the paradoxical development of clientelistic networks under macro-economic adjustment and restructuring. Liberalization, reduction of state intervention in favor of market mechanisms, privatization of services, and curtailment of union power further fragments society and heightens the need for support networks. When available, clientelism remained important throughout institutional revamping in Poland, Russia, Hungary, Brazil, Argentina, and Turkey.

In centralized polities, PCR have been depicted as a ‘lubricant’ to bypass the inefficient and rigid official system, constituting highly trusted informal problem-solving networks that provide material gains and support in situations of low institutional trust. In representative democracies, clientelism can be effective in power competitions, encouraging and rewarding party activists, once power is achieved, for effectively implementing policies. Patronage may become a restricted but legitimate procedure related to high office incumbents’ right to appoint followers to positions of responsibility. In other respects, clientelism remains controversial and open to allegations of corruption, due to its informal particularistic use of public resources. Often, it is ignored as long as possible or is

disguised as friendship, which is more acceptable in terms of the proclaimed ethos of modern equality.

Studies suggest that in post-industrial societies, patronage develops among professional and upper strata, rather than being restricted to the lower classes. Also, PCR are not confined to politics in the narrow sense, but proliferate as well in the arts, the academia, the church, the media, and even in business—whenever we deal with the power of appointment and the granting of access to benefits, goods, services, influence, and honors.

Changes in the perception of PCR are of systemic consequence if they result in the institutionalization of mechanisms through which citizens can press for entitlements without personal mediation. Such changes include: civil service reforms, non-partisan public systems, recognized charters of rights, controls over party fund raising, and non-partisan comptrollers as a prestigious and trustworthy branch of government. The functioning of these institutional mechanisms hinge on public support for a configuration of the public sphere structured around public accountability and formal responsiveness to turn more and more discrete issues into publicly negotiable and politically consequential.

Pattern Matching: Methodology

To the degree that products of the social and behavioral sciences merit the term ‘knowledge,’ it is because they are grounded in representations of the social world achieved by matching observations of that world with abstract concepts of it. Pattern matching is essential for attaining knowledge of everyday cultural objects such as food, clothing, and other persons. It is also indispensable for achieving knowledge of inferred entities in science—the size and brightness of distant stars, the existence and magnitude of latent psychological variables such as alienation or intelligence, and the structure of complex social processes such as social mobility, policy implementation, and economic growth. These and other inferred entities are known indirectly and vicariously, through a process of pattern matching (Campbell 1966).

1. The Concept of Pattern Matching

Pattern matching is a ubiquitous feature of knowledge processes in everyday life and in science. The use of pattern matching in everyday knowing, however, is different from pattern matching in mathematics, philosophy, and the social and behavioral sciences.

1.1 Rules of Correspondence

Rules of correspondence are prescriptions that enable the mapping of one set of objects on another. Objects in a domain, *D*, are related to objects in a range, *R*, according to a rule of correspondence such as: Given a set of *n* countries in domain *D*, if the object in *D* is a one-party system, assign the number ‘0’ from range *R*. If it is a multiparty system, assign a ‘1.’ Rules of correspondence perform the same matching function as truth tables in symbolic logic, pattern recognition algorithms in computer science, and the use of *modus operandi* (M.O.) methods in criminology. When a single rule of correspondence is taken to define fully and unequivocally the properties of an event or object—for example, when responses to scale items on an intelligence test are taken to define ‘intelligence’—pattern matching becomes a form of definitional operationism (Campbell 1969, 1988, pp. 31–2).

1.2 The Correspondence Theory of Truth

Until the late 1950s, philosophy of science was dominated by the correspondence theory of truth. The correspondence theory, the core epistemological doctrine logical positivism (see Ayer 1936), asserts that propositions are true if and only if they correspond

with facts. The correspondence theory also requires that factually true propositions are logically validated against formal rules of logic such as *modus ponens* ($p \supset q, p, \therefore q$) and *modus tollens* ($p \supset q, \sim q, \therefore \sim p$). To be verified, however, propositions must match facts (reality, nature). The correspondence version of pattern matching assumes a strict separation between two kinds of propositions—analytic and synthetic, logical and empirical, theoretical and observational—a separation that was abandoned after Quine (1951) and others showed that the two kinds of propositions are interdependent. Because observations are theory dependent, there is no theory-neutral observational language. Theories do not and cannot simply correspond to the ‘facts.’

1.3 Coherence Theories of Truth

The correspondence theory has been replaced by a more complex form of pattern matching, the coherence theory of truth, which has a number of versions (see Alcock 1996). In one version, often called the consensus theory of truth, beliefs are matched against other beliefs, with no requirement that they are tested empirically. Another version, realist coherence (Putnam 1981), requires that two or more empirically tested beliefs are matched. William Whewell’s *consilience theory of induction* is closely related to this (qualified) realist version of the coherence theory. A third version of coherence theory is methodological pragmatism (Rescher 1980). Here, beliefs must satisfy cognitive requirements including completeness, consonance, consistency, and functional efficacy, all designed to achieve optimally plausible knowledge claims. Other versions of coherence theory require the additional condition that the social circumstances under which empirically tested beliefs arise be taken into account. These other versions include ‘social epistemology’ (Fuller 1991) and the ‘sociology of scientific validity’ (Campbell 1994).

1.4 Statistical Estimation and Curve Fitting

Statistical principles, rules, or criteria are applied to achieve an optimal match between a curve and a set of data points or observations. An example is the *least-squares criterion* (the squared distance between observed and predicted values is a minimum or least value), where the match between the pattern supplied by a (linear or nonlinear) curve and a pattern of observations is approximate and probable, not certain as in pattern matching by rules of correspondence. The degree to which a curve and a set of observations match is summarized by coefficients of different kinds. Some of these represent the goodness-of-fit between

Figure 1
Statistical pattern matching: identical coefficients match different patterns (sources: Tufte 1983, pp. 13–14, Anscombe 1973)

curve and observations, while others represent the magnitude of error in pattern matching. Although coefficients are assessed according to a probability distribution, and given a p -value, the same observations can fit different curves; and the same curve can fit different observations. In such cases, pattern matching is as much a matter of plausible belief as statistical probability.

1.5 Context Mapping

Closely related to curve fitting is context mapping. Knowledge of contexts is essential for understanding elements within them. Context mapping, which is epitomized by the figure-ground relation in Gestalt psychology, also applies to the analysis and interpretation of statistical data. For example, observations in a scatterplot cannot be distinguished—in fact, they all look the same—when they are compared one-by-one, rather than compared as elements of the pattern

of which they are elements. Context mapping is important in statistical analysis. Coefficients that summarize relations among variables are usually misleading or uninterpretable outside the context provided by scatter plots and other *visual methods in statistics* (see Tufte 1983, 1997). Figure 1 illustrates how identical sets of correlation (r), goodness-of-fit (r^2) and probability (p) statistics match different patterns. Statistics are likely to be misinterpreted outside the context provided by scatterplots, each of which has its own visual signature.

2. Theory of Pattern Matching

The first systematic effort to develop a theory and methodology of pattern matching was that of psychologist and philosopher of social science, Egon Brunswik, a professor at the University of California, Berkeley between 1935 and his death in 1955. In this period, he and his close collaborator, Edward Tolman, developed different aspects of the theory of *proba-*

bilistic functionalism. To communicate this complex theory, Brunswik developed, initially for illustrative and pedagogical purposes, a *lens model* that was based on the optics metaphor of a double convex lens. The indispensable procedural complement of probabilistic functionalism and the lens model was his methodology of *representative design*.

2.1 Probabilistic Functionalism

Probabilistic functionalism is a substantive theory and methodology (philosophy of method) that focuses on relations of adaptation and accommodation between the organism and its environment. Probabilistic functionalism investigates the ways that interdependent, intersubstitutable, and uncertain cues about external environments are used to make judgments about these environments. Environments are not fully determined and uniform in their structures and processes of causality; rather they are uncertain, unstable, and *causally textured* (Tolman and Brunswik 1935). Probabilistic functionalism also studies the manner in which knowers learn about their environments by using informational cues or indicators, continuously creating new cues and revising or abandoning old ones. An essential aspect of these cues is that they are interdependent, multiply correlated, and intersubstitutable, features that require a process of knowing that is approximate, indirect, and vicarious. Darwinian in its focus on the adaptation of the organism to its environment, probabilistic functionalism seeks to understand how these two complex systems, the organism and the environment, come to terms with one another through a process of pattern matching.

2.2 The Brunswik Lens Model

Brunswik (1952) developed his 'lens model' to illustrate the probabilistic interrelations between the organism and the environment. The lens model represents processes of perception and judgment in terms of the optics metaphor of light entering (converging on) and exiting (diverging from) a double-convex lens. The lens model, while initially metaphorical in character, was later specified in what has come to be known as the 'lens model equation' (Slovic and Lichtenstein 1971, pp. 656–67):

$$r_a = R_e R_s G + C[(1 - R_e^2)(1 - R_s^2)]$$

The lens model supplies an achievement index, A , which measures the extent to which pattern matching has been achieved (see figure below). The achievement index ($A = r_{Y_e Y_s}$) is the correlation between the stat-

istical properties of an uncertain environment (Y_e) and the statistical properties of a judge's (or knower's) response system (Y_s). A matching index, G , is the correlation between the predicted knower's response (Y'_s) and the predicted criterion value for the environment (Y'_e). The lens model also estimates the degree to which indicators or cues are used in a linear or nonlinear fashion. In the equation above, the coefficient, C , is the correlation of the nonlinear residual variance in the multiple correlation coefficients R_e and R_s .

2.3 Representative Design

The methodology of *representative design* requires that experiments be conducted in realistic settings that are representative of an organism's typical ecology. Representative design is a radical departure from the classical experiment, in which one independent (treatment) variable is manipulated so as to assess its effect on a dependent (criterion) variable, with all other factors held constant through random subject sampling and statistical controls. Instead, experiments were to be conducted in natural settings, in environments that are unstable, dynamic, uncertain, and probabilistic. Such experiments require *situation sampling*, not merely the random sampling of subjects, because only the former optimizes the representative character of experiments. Representative design, in addition to its call to abandon the classical experiment, also required a rejection of the uniformity of nature presumption underlying Mill's Canons. Both ignored, and therefore failed to account for, the effects of the many interrelated contingencies that are causally relevant to experimental outcomes. Significantly, although Brunswik was an active participant in the Unity of Science Movement, and thus to some degree seems to have identified with logical positivism, he rejected the uncritical imitation of physics promoted by Vienna Circle positivists and the bulk of psychologists of his time. Psychology, and by extension other social and behavioral sciences, was practicing 'emulative physicalism' in its attempt 'to copy not only the basic methodological principles but also the specific thematic content of physics, thus nipping in the bud the establishment of (appropriate) methodological directives' (Brunswik 1952, p. 36; quoted in Hammond 1966, p. 55).

3. Methodology Development

Probabilistic functionalism and representative design have influenced the contributions of several highly influential scholars who studied with Brunswik and Tolman at Berkeley. Some of these contributions are principally theoretical, for example, social judgment theory (Hammond 1980) and evolutionary epistem-

Figure 2

The Brunswik lens model (source: adapted from Slovic and Lichtenstein 1971)

ology (Campbell 1974, 1996). It is in the area of methodology development, however, where many of the most important contributions have been made.

3.1 The Lens Model and Clinical Inference

The lens model, backed by probabilistic functionalism and representative design, has been at the center of an entire research tradition on clinical inference (see Hammond 1980, 1996). Significantly, many of the most important lens-model studies have been applied studies conducted with the aim of improving learning, judgment, and behavior. In this tradition, research problems have turned on the question of how pattern matching can explain differences in achievement (predictive accuracy) among individuals with different levels of experience, including novices as well as experts. The right side of the lens model (Fig. 2) is used to predict a 'distal' environmental variable (e.g., future university enrollments) by regressing individual judgments about the distal variable on a set of interrelated and mutually substitutable informational cues (e.g., unemployment, income per capita, changes in age structure). In turn, the left side of the model focuses on

predictions of that same distal variable derived from a multiple regression analysis in which the same cues (although here they are 'indicators' or 'variables') are predictors.

An important variant of this basic design is one where members of different professional groups—for example, scientists and lawyers in some area of science policy—occupy the right and left sides of the lens model. Either group may be taken as a reference class, and the calculation of the matching index, M , expresses the degree to which their prediction patterns match. In applied contexts, the judgments of each participant (subject) are externalized and made available to other participants. In addition, the way that each participant uses information (e.g., in a linear or nonlinear fashion) is estimated through a process of 'policy capturing.' These and other applications of the lens model have been designed to improve learning and judgments in contexts ranging from R&D planning, police work, gun control, and human factors research. The lens model has a computerized decision support program ('Policy PC') and its theoretical foundation has been redefined from social judgment theory to *cognitive continuum theory* (Hammond 1996).

3.2 Methodological Triangulation

The recognition that nature is not directly observable—that our predicament as knowers is that we must employ many intercorrelated and mutually substitutable proximal cues to infer the properties and behavior of distal objects—means that science and other forms of ‘distal knowing’ involve a process of pattern matching through triangulation (Campbell 1966). A number of important methodologies were developed on the basis of this recognition. One of these is the substitution of definitional operationism with multiple operationism, a substitution that involves triangulation among two or more operational definitions, each of which is seen as approximate, fallible, and independently imperfect. A second development was the expansion of multiple operationism to include theoretical constructs as well as methods for their measurement. Here the multitrait-multimethod matrix reconceptualized *construct validity* as a ‘trait-method unit,’ and introduced the concepts of *convergent validity* (multiple measures of the same construct should converge) and *discriminant validity* (multiple measures of different constructs should diverge) that parallel aspects of Brunswik’s metaphor of a double-convex lens. The 1959 article in which the multitrait-multimethod matrix was first published (Campbell and Fiske 1959) is reputed to be one of the most highly cited in the social and behavioral sciences. A third development is multiple triangulation, including critical multiplism (Cook 1984), which involves the inclusion of multiple theories, methods, measures, observers, observations, and values. These and other forms of methodological triangulation enable ‘strong inference’ in the natural and social sciences (Platt 1964) and affirm that the vast bulk of what is known is based on processes of indirect, vicarious learning.

3.3 Quasi-Experimental Design

The methodology of representative design, as we have seen, rejected the classical experiment on grounds that it is unrepresentative of the usual ecology of in which knowers function. Representative design was carried forward into the applied social sciences by Donald T. Campbell and associates (Campbell and Stanley 1963, Cook and Campbell 1979). Their quasi-experimental designs were contrasted with the classical laboratory experiments in which: an outcome variable is explained by a single independent (treatment) variable (the so-called ‘rule of one’); other possible explanations are ruled out through random selection of subjects; and the experimenter has virtually complete control over all contingencies. Quasi-experimentation, although it may use some of the features of classical experiments (e.g., repeated measures and control groups) should be contrasted with experiments in the analysis of variance tradition of Ronald Fisher, who

envisioned experimenters who ‘having complete mastery can schedule treatments and measurements for optimal statistical efficiency, with the complexity of design emerging only from that goal of efficiency. Insofar as the designs discussed in the present chapter become complex, it is because of the intransigency of the environment: because, that is, of the experimenter’s lack of complete control’ (Campbell and Stanley 1963, p. 1).

Because quasi-experimental designs are intended for research in settings in which numerous contingencies are beyond the control of the experimenter, many rival hypotheses (alternative explanations of the same outcome) can threaten the validity of causal claims. These rival hypotheses are organized in four sets labeled threats to statistical conclusion, internal, external, and construct validity (Cook and Campbell 1979, Chap. 2). Plausible rival hypotheses must be tested and, where possible, eliminated. This process of eliminative induction is a qualified form of Mill’s *joint method of agreement and difference* and Karl Popper’s *falsificationist* program. Quasi-experimentation is part of a wider evolutionary critical-realist epistemology (see Campbell 1974, Cook and Campbell 1979, Shadish et al. 2000) according to which knowers adapt to real-world environments by using overlapping and mutually substitutable informational sources to test and improve their knowledge of indirectly observable (distal) objects and behaviors. Quasi-experimentation is a form of pattern matching.

3.4 Pattern-Matching Case Studies

When quasi-experimental designs are unfeasible or undesirable, several forms of case study analysis are available. Each of these involves pattern matching.

(a) *Theory-Directed Case Study Analysis*. When a well-specified theory is available, a researcher can construct a pattern of testable implications of the theory and match it to a pattern of observations in a single case (Campbell 1975). Using statistical ‘degrees of freedom’ as a metaphor, the theory-directed case study is based on the concept of ‘implications space,’ which is similar to ‘sampling space.’ Testable implications are functional equivalents of degrees of freedom, such that the more implications (like a larger sample) the more confident we are in the validity of the conclusions drawn. But because theories are almost inevitably affected by the culturally acquired frames of reference of researchers, the process of testing implications should be done by at least two ‘ethnographers’ who are foreign to and native to the culture in which the case occurs. The process of triangulation among observers (ethnographers) can be expanded to include two (or more) cases.

(b) *Qualitative Comparative Case Study Analysis*. Two or more cases are compared by first creating a list of conditions that are believed to affect a common

outcome of interest (see Ragin 1999, 2000). The multiplication rule, r^m , is used to calculate the number of possible ordered configurations of r categories, given m conditions. When $r = 2$ and $m = 4$, there are $2^4 = 16$ configurations, each of which may involve causal order. These configurations become the rows in a 'truth table,' and each row configuration is sequentially applied to an outcome with r categories (e.g., successful vs. unsuccessful outcome). Because this method examines possible configurations, and two or more different configurations may explain the same outcome in different cases, the qualitative comparative method should be contrasted with traditional (tabular) multivariate analysis. The qualitative comparative method matches configurable patterns that have been formally structured by means of set theory and Boolean algebra against patterns of observations in case materials.

(c) *Modus Operandi Analysis*. When quasi-experimental research is not possible, *modus operandi* methods (see Scriven 1975) may be appropriate for making causal inferences in specific contexts. *Modus operandi* methods are based on the analogy of a coroner who must distinguish symptoms and properties of causes from the causes themselves. The first step is to assemble a list of probable causes, preferably one that is quasi-exhaustive. The second is to recognize the pattern of causes that constitutes a *modus operandi*—modus refers to the pattern, while operandi refers to specific and 'real' causes. The *modus operandi* of a particular cause is its characteristic causal chain, which represents a configuration of events, properties, and processes. *Modus operandi* analysis has been formalized, partially axiomatized, and advanced as a way to change the orientation of the social and behavioral sciences away from abstract, quantitative, predictive theories toward specific, qualitative, explanatory analyses of causal patterns (Scriven 1974, p. 108).

4. Conclusion

To date, the only thorough and systematic theory of pattern matching is that of probabilistic functionalism and its methodological complement, representative design. Pattern matching is essential for achieving knowledge of external objects and events, of causal regularities that have been repeatedly recognized as the same, of the character of discrete observations formed by viewing them in context, of the fit between a curve and a set of data points, of the extent to which theories cohere, and of the degree to which theory and data correspond. Underlying all pattern matching methodologies is a shared recognition that knowing in science is profoundly indirect, vicarious, and distal.

W. N. Dunn

Pavlov, Ivan Petrovich (1849–1936)

Ivan Petrovich Pavlov is recognized as one of the most renowned of Russian scientists and is clearly the best known Russian physiologist of his era. His work on the physiology of the digestive system was well respected by his colleagues worldwide during his lifetime. This respect earned him the first Nobel Prize awarded to a physiologist and the first to a Russian scientist in 1905. Although the excellence of his work on the physiology of the digestive system is well recognized, Pavlov is even better known for his investigations into what he termed ‘conditioned reflexes.’ This work has had a worldwide impact on the fields of learning and memory, psychology, neuroscience, etc. Pavlov’s life can be divided roughly into three phases. The first, including his early years, was a phase in which Pavlov received his early training in physiology and medicine. A second investigational phase was one in which his work on the physiology of the digestive system was done. The third includes his work, for which he became most famous, on conditioned reflexes.

1. Pavlov’s Early Life

Ivan Petrovich Pavlov was born on September 14, 1849, in the small town of Ryazan, about 100 miles southeast of Moscow. He was the eldest of five children. His father was a priest in one of the poorer parishes. Thus, during Pavlov’s early life he lived in extreme poverty. Nevertheless, the life of Pavlov and his siblings was apparently intellectually rich and their father instilled a love of learning in each of his children. Pavlov entered the ecclesiastical high school of Ryazan, and from there to the local seminary, ostensibly to pursue an ecclesiastical career, as his father and other members of his family had done. Pavlov thus entered school during the Russian Cultural Revolu-

tion of the 1860s and therefore was exposed to the leaders of this revolution, such as Turgeanyev, Doskovsky, Tolstoy, etc. However, he was apparently most heavily influenced by Pisarev, from whom he learned of Darwin’s theory of natural selection and the famous Russian physiologist Sechenov, who had just published *Reflexes of the Brain* in 1896. It is clear that these kinds of influences on Pavlov steered him in the direction of science and consequently he left the ecclesiastical seminary and entered the Mathematics-Physics Department at St. Petersburg State University.

In 1875 Pavlov graduated from the University with a degree in natural sciences. However, due to his interest in physiology he started work as an assistant in the Department of Physiology in the Medical Surgery Academy (now the Military Medical Academy) and in 1879 received a medical diploma. He was then recommended for an appointment with Andre Botkin, who was the most renowned clinician in St. Petersburg at the time. Botkin assigned Pavlov the task of heading his recently established experimental research laboratory. Since Botkin had little interest in experimental work, Pavlov was able to work pretty much independently on problems of his choice. He worked here until 1890. He was heavily influenced by Botkin’s theories on the role that the nervous system plays in the regulation of physiological function, and it was here that Pavlov began his studies of the peripheral nerves of the heart and where in 1883 he successfully defended his doctoral dissertation in this area.

During this period of time he also became acquainted with a small circle of friends including another university student, Seraphima Vasilievna, who was in her last year at the Pedagogical Institute. They were married in 1881. During the first years of their married life they lived in extreme poverty. After a first miscarriage, Seraphima gave birth to a son but he also died the next summer. They did, however, later have four children (three boys and a girl) and, based on Seraphima’s memoirs published after Pavlov’s death, apparently enjoyed a happy family life. In 1883 Pavlov spent two years working abroad in the laboratories of Heidenhain and Ludwig in Germany. On his return to St. Petersburg, he resumed his work in Botkin’s laboratory and in 1890 was appointed Professor in the Pharmacology Department at the Military Medical Academy. Five years later he joined the Physiology Department there, which he headed for the rest of his career. He was also later appointed the Head of the Department of Physiology in the newly established Institute of Experimental Medicine. Pavlov worked in his laboratory there until his death at the age of 87 in Leningrad on February 27, 1936.

2. Pavlov’s Work on the Digestive System

Pavlov did most of his research on the physiology of digestion during his early years at the Institute for

Experimental Medicine. Here he was able to develop his surgical skills with chronic experiments, which he advocated over the acute experiments that were typically done in physiology at that time. Pavlov believed that the study of the entire organism in as normal a state as possible was crucial to understanding physiological systems. Moreover, he was an excellent surgeon and became quite experienced in developing surgical procedures that allowed his dogs to fully recover. In such animals the digestive processes could be studied under normal conditions. As a consequence of this approach to physiology he developed a ‘stomach pouch,’ which involves isolating a portion of the dog’s stomach, so that it can be directly observed by the experimenter. Unlike previous researchers, the nervous input to the isolated portion of the stomach was intact in the ‘Pavlov Pouch.’ Using this preparation Pavlov could observe the digestive juices and enzymes that occurred as a result of normal food intake, or after direct placement of food into the stomach. It was the comparison of these two states which led to Pavlov’s interesting discovery that food placed in the mouth as a normal consequence of eating, produced a significantly larger amount of gastric secretion than when food was placed directly in the stomach. Moreover, when animals were sham fed, viz. when the normal intake of food through the mouth was allowed to take place but the food was diverted externally, a significant amount of gastric secretion occurred, even though the food never reached the stomach.

It was these types of experiments, which led to Pavlov’s pioneering discoveries regarding the control of the digestive system by its autonomic nervous input, primarily the vagus nerve. He showed for example that a major consequence of this neural control involves both gastric and pancreatic secretions before any food actually reaches the stomach, by the sight of the food bowl for example, or other stimuli previously associated with eating. These ‘psychic secretions’ turned out to be of great importance for digestion and led to Pavlov’s major conclusions regarding what came to be known as the doctrine of nervism, in which the major tenet states that the physiological control of bodily systems is primarily through its nervous input. This work culminated in the publication of *Lectures on the Work of the Digestive Glands* in 1897, later translated into English in 1910 (Pavlov 1910). However, it was during this same period of time that two British physiologists, W. Bayliss and E. J. Starling, demonstrated that the secretin of the pancreatic enzymes was primarily due to release of a substance by the intestines during eating, which came to be called secretion. These investigators thus claimed that the doctrine of nervism was invalidated by their discoveries. However, as is typically the case with two opposing theories of biological function, both experimental outcomes were eventually confirmed. The new science of neuroendocrinology thus came to be

established, and it is now widely accepted that nervous control over hormonal output is a ubiquitous aspect of physiological function.

3. Pavlov’s Work on Conditioned Reflexes

As a result of his work on the digestive processes, as noted above, Pavlov also observed that non-food stimuli that became associated with food were able to elicit salivary secretions, and to a lesser extent digestive secretions, even though no food was actually present in the mouth. These ‘psychic secretions’ came to form the basis for the remainder of Pavlov’s work and resulted in his experiments moving in a new direction, which caused an almost complete cessation of work on the digestive system proper. However, Pavlov believed that by studying ‘psychic secretions,’ which he referred to as ‘conditioned reflexes,’ he would be able to demonstrate in an objective manner how the brain controls adaptive behaviors. Pavlov developed a salivary fistula, similar to the stomach pouch, in which the release of salivation in the mouth was directed through a tube to a container outside the mouth. Through this technique he was able to discover the amount and kinds of salivary secretions that were produced by different kinds of sensory stimuli.

Using these techniques Pavlov began the study of a new kind of learning, which has come to be known as ‘classical’ or ‘Pavlovian’ conditioning. Classical conditioning occurs whenever a neutral stimulus acts as a signal for a forthcoming significant event. Thus, for example, in one of Pavlov’s original experiments a pure tone, a metronome, or some other equally neutral stimulus signaled to a dog that it was about to receive an appetitive stimulus, i.e., meat powder (see Pavlov 1927). In Pavlov’s experiments this neutral auditory stimulus was termed the conditioned stimulus (CS) and the meat powder the unconditioned stimulus (UnS). The UnS always elicits what Pavlov referred to as an unconditioned response (UR), viz. salivation in response to the meat powder. The behavior in which Pavlov became most interested, however, was not increased salivation in response to the meat powder, which he had previously studied intensively, but the new learned response to the neutral CS. This response also consisted of salivation, but in this case salivation in response to the initial neutral auditory stimulus, which resulted from its consistently preceding the meat powder over many CS/UnS presentations. This new learned response was referred to as a conditioned response (CR) and was thought to be only temporary and required reinforcement by the UnS for its maintenance. The UnS is thus often referred to as a reinforcer, since it reinforces the new response to the CS.

It should be noted that the CR does not, however, always resemble the UR as is the case with the original salivation experiments, which Pavlov reported. Indeed

often the CR appears to be opposite to the UR. For example, the autonomic changes associated with the contextual cues that signal drug administration, an often-studied type of classical conditioning, are opposite in direction to those produced by the drug itself (Siegel 1979) and the heart rate CR to CSs that signal aversive UnSs consist of bradycardia, whereas the UR to these same aversive stimuli alone consists of tachycardia. There are many other experimental operations that have been studied since the time of Pavlov, which produce similar new responses to an original neutral stimulus that is always followed by either a noxious or appetitive event. Pavlov thus developed a new experimental methodology for studying the role of the brain as it initiates new behaviors enabling animals to adapt to their environmental circumstances.

One of Pavlov's greatest contributions to physiology was to emphasize that the nature of the 'psychic secretions,' which were previously thought to be in the realm of psychology, could be objectively studied by physiologists through the conditioned reflex method. He thus believed that the true road to understanding brain function and therefore human behavior was through the objective physiological techniques, which he had developed. In fact Pavlov went on to consider a range of higher level functions such as thinking, reading, emotional reactivity, etc., in terms of conditioned reflexes. Using the ideas of cortical excitation and inhibition, which he studied extensively using the conditioned reflex methodology, he was thus able to explain many complicated behavioral phenomena, such as the neuroses and other psychiatric disturbances. Although Pavlov's influence on experimental psychology has been extensive and dramatic, as detailed in Sect. 4, many of the details of his theoretical interpretations have since been found to be lacking. Nevertheless the basic operational procedures for determining the effects of a signal on brain processing has been extremely influential in studying brain function.

4. Pavlov's Influence on Modern Psychology

During his lifetime and immediately thereafter, Pavlov had a tremendous influence on physiology and the study of brain function. Many students were drawn to his laboratory during the early part of the twentieth century to study the basic laws governing the activity of the brain, and during this period of time Pavlov received worldwide acclaim and recognition. Pavlov's work was little affected by the Russian Revolution, which was also ongoing during this time. He maintained a skeptical attitude regarding politics and government, but nevertheless his worldwide recognition led the Communists to continue to fund his research at high levels. Thus, the Soviet Union became known for its support of the study of physiology, and

it was during this time that a great center for the study of physiology with many distinguished workers was developed in the Soviet Union, primarily under Pavlov's leadership.

It was his influence outside the Soviet Union, however, that resulted in Pavlov's most notable successes in science, primarily in the field of psychology, which Pavlov had previously rejected. Thus the conditioned reflex methodology was instrumental to the development of the behavioristic movement in psychology in the early part of the twentieth century. John Broadus Watson, one of the major pioneers in the development of behaviorism, utilized the conditioned reflex methodology to explain the entire subject field of psychology, which consisted, according to behaviorists, in the study of overt behavior without reference to subjective phenomena such as cognitions, learning, feelings, etc. The publication of *Psychology as the Behaviorist Views It* (1913) by Watson thus became instrumental in informing American and English scientists of Pavlov's work. The translation of Pavlov's *Conditioned Reflexes* (1927) by Anrep made his work available to English speaking scientists. As a result, experimental psychologists began to explore the new conditioned reflex methods for studying behavior at several academic centers in the USA. As was noted by Babkin (1949), however, much of the work done by the American researchers focused on skeletal reflexes, as opposed to the visceral reflexes, to which Pavlov and his students had previously devoted most of their work.

One of the basic experiments developed by American psychologists was the classical eyeblink-conditioning paradigm. Using this methodology human or animal subjects are presented with a corneal airpuff, which causes reflexive closure of the eyelids. However, when this unconditioned stimulus is preceded by a conditioned stimulus such as a light or pure tone, eventually subjects began to show anticipatory eyeblinks during the conditioned stimulus, which occur even though the corneal airpuff is not presented. This paradigm came to be used extensively in the early 1940s and 1950s as behaviorism began to gather momentum. Its success in the hands of the American psychologists led to the de-emphasis on visceral changes as conditioned responses in the USA. However, Horsley Gantt, who had previously studied with Pavlov, demonstrated in his Johns Hopkins laboratory that both visceral and skeletal responses could be studied in the same organisms, and that the two responses differed greatly in their acquisition and the conditioning parameters required to elicit learning (Gantt 1960). Much of this early work on classical conditioning was, however, overshadowed by the emphasis given to operant conditioning by other behaviorists, such as B. F. Skinner and Clark Hull. Thus, it was only during the early 1960s that classical conditioning became a popular technique for studying behavior. This was due to the development by I.

Gormezano of the classically conditioned nictitating membrane response in the rabbit (Gormezano 1966). The nictitating membrane is a third laterally moving eyelid found in the rabbit and some other mammals (e.g., cat). Using this animal preparation Gormezano and his students were able to demonstrate the parametric circumstances under which this kind of learning takes place and what kinds of visceral changes accompany them, e.g., conditioned changes in heart rate, blood pressure, etc. The popularity of this technique became even greater when integrated with the simultaneously developing field of behavioral neuroscience. Classical conditioning offers several advantages for studying concomitant brain function as well as new learned behaviors. For example, concomitant electrophysiological recording from single neurons in specific parts of the brain have led to the discovery that different brain structures are involved in visceral versus skeletal learning (Thompson 1991). Moreover, more recent brain scanning techniques in humans have demonstrated that even during simple classical eyeblink conditioning activation of several specific areas of the brain, which are known to be involved in learning and memory processes, occurs (e.g., Blaxton et al. 1996).

Thus the use of the conditioned reflex techniques originally developed by Pavlov has come to be one of the major methods used in studying brain-behavior relationships in modern psychology. Pavlov's contribution to this new technology was at a basic level and much of his earlier conclusions regarding the results of his manipulations were, of course, erroneous. However, his contributions we now know were instrumental to the development of modern psychology.

Pay and Compensation, Psychology of

1. The Design of Compensation

In industrialized countries the compensation of managers and employees usually consists of three or four component parts. One part is rooted in the value of the job which is held, providing for the fixed base pay (wage or salary). The second part reflects an assessment of the effort exerted or the performance result, often called the 'performance bonus.' The third part deals with 'secondary labor conditions,' such as health insurance, retirement provisions, etc. Firms in several countries offer still additional benefits—perquisites—to their personnel (or merely their managers), such as car lease, lower interest rates on mortgage loans, etc. However, there are sizable differences between (and often also within) countries regarding the proportional contribution of each of these parts to an individual's total compensation.

Yet the common design in the composition of compensation in most countries is remarkable. This cuts across considerable differences between countries in industrial relations, wealth and welfare, and culture. Why? Probably partly because traditions in trades and industrial sectors, laws and regulations, and the ideas of labor unions and employers' federations are playing a role. And also, in all likelihood, partly because of some widely shared beliefs and attitudes about the differential impact of the various compensation components upon the work behaviors of organization members. This borders on the psychological perspective on pay, which addresses the impact of compensation upon the attitudes and work behaviors of organization members, both individually and as part of teams or larger work units. More particularly, the psychological study of pay and compensation aims to identify determining variables at different levels of analysis (such as pay system, or strength of individual expectations), moderating aspects (such as the nature of the task), and individual, group, or company-wide results (such as performance or productivity).

This perspective determines the design of this article. First, the nature of the four compensation components

is further described, in relation to some characteristic beliefs and attitudes on how they operate. Next, a few psychological theories on pay and compensation will be discussed. Finally, some implications for psychological research on pay and applications in practice are discussed.

2. Four Components and Concomitant Beliefs

Although the background of the compensation components is discussed in relation to what is characteristically expected regarding each of them, I do not imply that a company's management is always engaged in decision making along these lines. Indeed, pay systems and compensation provisions may have been introduced in a firm for reasons of tradition, imitation of other companies, or merely because alternative choices were not considered.

2.1 Base Pay

In most countries base pay constitutes the main part of an organization member's take-home pay. Yet there may be sizable differences in the proportion of base pay between trades and job categories. Traditionally, the pay of sales representatives is determined to a large degree by actually achieved sales figures. Managerial pay is characterized by a proportionally lower base-pay component than nonmanagerial pay, in particular for senior managers (Rynes and Bono 2000). Base or job pay is often set through a system of job evaluation (cf. Thierry and De Jong 1998). Increasingly, international wage and salary surveys are used, as well as more subjective impressions of the going rate on the market. Base-pay levels are usually fixed as long as the term of individual contracts or collective agreements applies.

Often the fixed base-pay level is a reflection of the belief that stability in pay contributes to individual feelings of security. It is also supposed that without the need to worry about their pay, working people will concentrate more upon the content of their tasks. Moreover, a high base-pay level may imply the notion that work motivation is considerably more affected by nonmaterial needs and goals than by material ones. Possibly this results in more intrinsic motivation (cf. Deci and Ryan 1985, Deci et al. 1999). Characteristically, levels of base pay increase each year, usually through an additional 'step' on the wage or salary scale. Although the latter increase may have been awarded to make up for increased costs of living, it often also mirrors the idea that more maturity (i.e., getting older and becoming more experienced) goes along with better performance.

2.2 Results-oriented Pay

This category, also called 'pay for performance,' is host to a variety of systems and forms. Results may be

derived from individual performance appraisal sessions, in which rather abstract characteristics (such as initiative or creativity) are interpreted and considered. Results may also refer to quantitative outcome scores, for instance the number of new bank clients secured and the volume of their investments. Results may relate to individual data, but also to those of teams, units, and whole organizations (such as sales volume or net profit). These data may be provided weekly, monthly, or over a much longer period. The 'pay' is often allocated in the form of a bonus (paid only once), but it may also be given as an extra, 'structural' salary increase. The amount of results-oriented pay may be rather modest (e.g., 3 percent), but it may also exceed the base pay's proportional part of total compensation (see, more extensively, Rynes and Bono 2000, Bartol and Locke 2000, Thierry in press).

What is results-oriented pay supposed to effectuate? A widespread belief holds that it stimulates an individual's work motivation, effort, or performance. Research evidence (Thierry in press) shows that this can be frequently supported, although there are also many instances of failure. Another assumption is that results-oriented pay is perceived by many employees (and managers) as more fair, since it compensates for perceived individual and group differences in effort and/or performance (Van Silfhout 2000). Organizations in which this assumption is endorsed usually assign a particular budget to covering these merit-pay expenses. Making pay dependent upon performance results may be used to cut costs as well. Moreover, it may be used to feed performance data back to employees, and, more generally, for communicating with them.

More than is the case for other compensation components, the phase of preparing and introducing results-oriented pay is rather complicated and time consuming. It may imply that a part of the work flow is being organized more efficiently, that norms and targets are being established, that results are being fed back, that employees and managers are being consulted about the new system, and so forth. In particular, when better performance results have been reached, a point of concern is that these activities may have contributed to these results rather than the linkage between performance and pay.

2.3 Secondary Labor Conditions

There are huge differences between countries in the handling of secondary conditions. Traditionally, companies in the USA offered a very modest package to their members—leaving to them the decision whether or not further to insure themselves—whereas companies in northwestern Europe provide encompassing social security within the framework of collective labor agreements. In the latter case, conditions relate,

for example, to health insurance, disability coverage, retirement benefits, or unemployment provisions. These are intended to help working people to compensate for risks they run in their work and lives. Yet, such social security packages are not very well tailored to the individual organization member's conditions and wishes. Moreover, because of health research and technological innovations, there is a continuing trend to expand the number and the nature of social security provisions.

It is therefore an interesting development that the 'cafeteria plan' is gaining popularity on both sides of the Atlantic (Barber and Bretz 2000). According to this plan (also called 'à la carte' or 'flex-pay') organization members may exchange one or more standard labor conditions for optional ones. In US companies this plan was initiated some 40 years ago, in order to gradually expand social security coverage. Consequently, managers and employees may tailor their social security package to their particular conditions, which may lead to more utility against similar or lower costs for the company. More recent European experience, for instance in the UK and The Netherlands (cf. Thierry 1998), indicates that organizations think the plan equips them better as competitors in the labor market for 'flexible, employable' applicants. They may also express their particular culture and climate in their choice of alternative provisions. Consequently, their members are expected to be more motivated, to work better, to be more satisfied with their pay package, and to have more knowledge of their compensation components. Research evidence shows that only the latter two expectations are frequently met (Thierry 1998, in press).

2.4 Perquisites

Organizations may offer their personnel (or selected categories, such as senior managers) still further labor conditions. Early examples came in the manufacturing sector, in which an allowance for occupational clothing or cloth cleaning was sometimes provided. Current practices include (mobile) phone cost coverage, car leasing, lower mortgage interest, shares on the stock market, options on company shares, and so forth. Some of these options may be available through a cafeteria plan (see Sect. 2.3). Perquisites were provided to make up for particular inconvenient conditions and occupational costs, but current objectives relate to attracting potential applicants on the labor market and, in particular, to keeping qualified personnel within an organization.

2.5 Beliefs in Perspective

The preceding overview of compensation components shows that each component is characterized by rather

distinct beliefs and expectations about how compensation may affect the attitudes and work behaviors of managers and employees. Yet an important issue is whether these beliefs are founded in concepts relevant to psychological theories on pay and compensation. Some of these will be reviewed here (more extensively in Thierry in press), but the various beliefs are to be recognized in almost all objectives of pay (cf. Thierry 1998):

- to *attract* applicants from the labor market;
- to *retain* qualified personnel within an organization;
- to *motivate* managers and employees to perform well;
- to *alert* managers and employees to engage in different performance behaviors in times of change;
- to *balance* inconvenient working conditions with an attractive award;
- to *prevent* industrial conflicts (or to solve these where they have occurred);
- to *cut down* labor costs; and
- to further a distinct, recognizable business unit or group *culture*.

3. Some Psychological Theories on Pay

Most psychological theories on pay have not been explicitly designed for understanding and predicting people's behaviors and attitudes regarding pay. Rather, they have been derived from more general theories, for instance regarding motivation. The theories selected here stem from both 'categories.'

3.1 Expectancy Theory

This theory concerns matters of work motivation (Vroom 1964, Van Eerde and Thierry 1996), in particular the choice process of an employee being faced with the necessity or the opportunity to mark a course of action among alternative activity patterns. Suppose that an employee considers whether to spend all their energy and resources in making the current job a great success, hoping for a promotion in the not too distant future, or whether to apply for a job in another organization, which involves taking several courses in order to become more employable. Expectancy theory holds that three cognitions determine the eventual choice:

- the probability that a particular level of effort leads to a specific level of performance;
- the probability that this performance level causes the attainment of particular outcomes; and
- the attractiveness of those outcomes.

The alternative with the highest subjective utility for the employee will be chosen. Thus, assuming that a job elsewhere is slightly more attractive than a promotion, the employee may nevertheless opt for the internal

promotion, since they estimate the probability of getting access to courses that will increase their employability as much lower than turning the current job into a success.

Lawler (1971) has applied the last two cognitions to the importance of pay. Accordingly, its importance to an employee is a function of:

the extent to which pay is perceived as offering resources for satisfying particular needs or goals; and
the importance of these needs and goals to that employee.

In other words, the more pay is considered to be instrumental in getting more security in life (e.g., through purchasing an insurance policy), in being recognized by other people, and in gaining more independence—to mention some examples—and the more these needs are important to the individual employee, the more important pay has become. Pay is not important in itself: it may be a stronger or weaker vehicle for reaching other outcomes.

One implication bears upon the system of results-oriented pay: in order to be effective, it is necessary that an organization member perceives a clear 'instrumental' link between one or more particular performance levels and specified amounts of pay (e.g., Van Silfhout 2000).

3.2 Equity Theory

Expectancy theory is focused upon the individual human being, engaged in means-to-end relationships. Is that individual affected by one or more others, by smaller or larger social networks in the choice-making process? Yes, according to Ajzen and Fishbein's theory of reasoned action (1980), in which the individual's beliefs about what others think he or she should do are supposed to affect the choices he or she make. Equity theory (Adams 1963, 1965) includes 'social others' indirectly in the balance between contributions and inducements. Adams holds that an individual strives for such a balance *relative* to the balance that individual perceives between contributions and inducements as applying to a referent. A referent may be one or more human beings, a particular group, an organization's policy, and that individual at an earlier or later stage of their career. Contributions relate to long-term investments and short-term costs, such as education, abilities, and effort. Among inducements are task performance, recognition, and compensation. Equity is achieved when the person's perceived contributions-inducements ratio is equal to their perception of the referent's ratio. An unequal balance results in dissonance and inequity.

A typical setting would be an experiment in which the ratio between a person's effort (to perform a task) and pay is compared with the effort-pay ratio as perceived to apply to the referent. A high level of

inequity would be the result when the person perceives their own situation in terms of high effort for low pay, and the referent's ratio as low effort for high pay. Obviously, the person would then be motivated to restore an equitable balance. But how? That is difficult to predict. Available strategies are: effecting change in contributions and/or inducements; changing the referent; cognitively reinterpreting the inequitable situation; or leaving the organization. Harder (1992) showed in a study of baseball and basketball players that under-rewarded players tended to opt for utilitarian, egotistic behaviors that were thought to lead to future higher rewards.

3.3 Reflection Theory

This theory specifies the meanings of pay or compensation. A basic notion is, again, that pay has no significance in itself, but that it acquires meaning to the extent that it conveys information that is vital to an individual's self-identity. Accordingly, pay 'reflects' information about events in other fields. Four categories of meaning are distinguished:

(a) *Motivational properties*. This category is derived from expectancy theory (Sect. 3.1). Pay is meaningful to the extent that it is considered to be instrumental in satisfying a person's motives.

(b) *Relative position*. This bears upon two aspects. One reflects feedback about task performance relative to the targets set. Pay may signal whether particular corrective actions are necessary. The other aspect is social comparative: pay reflects how well a person is doing in comparison with others inside and/or outside the company.

(c) *Control*. Pay may reflect the amount of control the individual exerts on their environment (both the social network and material means) as well as the extent to which they are controlled by the environment.

(d) *Spending*. Here pay reflects the utility of goods and services purchased by the individual, and the ease or hardship with which this occurred.

Scales are available for measuring these meanings. The core of reflection theory is that the more an employee or manager reads meanings into their pay, the more their performance and satisfaction with pay is affected (Thierry 1998, 2001). Obviously, the design of a pay system and the manner in which it is administered are among the variables that influence the meanings pay may have.

4. Conclusion

An important question raised in the introductory section is whether the beliefs and expectations which seem to be basic to the four compensation components are grounded in psychological theories on pay. Just

three theories could be discussed; nonetheless, their tenets are rather representative. Expectancy and reflection theory provide some ground for results-oriented pay, in particular regarding the importance of unambiguous performance leading to pay perceptions. Yet it is not clear how these perceptions should be structured in the case of group performance; possibly equity theory's notion on contribution—inducement ratios should also be considered. The belief embedded in the concept of base pay—that stability and predictability of pay may cause employees and managers to be focused more upon the content of their work—does not take full account of the meanings of pay (put forward in reflection theory) relative to the meanings of nonmaterial work characteristics. This is clearly in need of more research. Continued research on cafeteria plans, including perquisites, is vital, in order to learn whether this compensation component meets its expectations. All in all, however, beliefs and expectations about compensation in practice are not so much missing the point as more outspoken than psychological theory would require them to be.

Peace

The major cases of violence and peace relate to the way the human condition is cut through by fault lines, dividing humans and nature, normal people from deviants, different genders, generations, races, classes, nations, states. Each border defines at least two categories, self and other. The violence can be direct violence intended by the self to attack the basic needs of the other; or structural violence, also preventable, not intended, usually slower, but at least equally devastating. If the other is dehumanized to a category, we end up with genocide—massive category killing. With two types of violence and eight fault lines we get a 16-fold discourse, as shown in Table 1.

Most of the time and in most places there is 'narrow peace' or an absence of direct violence across most fault lines, but not 'broad peace' or an absence of direct and structural violence. Different cultures view peace differently as descriptive (how is peace possible) or prescriptive (how could peace be possible).

The following is a review of the theories of peace of six macrocultures, or civilizations. Of the six, three are from the Occident, defined here as the cultural space spanned by the Abrahamic religions of the Book, the *kitab*, or Old Testament: Judaism, Christianity, Islam. We start with two Europes, secular Europe—the Europe of antiquity—and then Christian Europe. We then move East to West Asia (I have not designated this as the 'Middle East,' which is a Western European perspective) with Judaism, Islam, and the cradle of Christianity. Continuing eastward we come to South Asia, with what is conveniently called 'Hinduism' and its offspring, Jainism and Buddhism. And further east, in East Asia there are the Chinese and Japanese cultural amalgams with a Confucian core, Buddhism, and then Taoism in China and Shinto in Japan. We

Table 1
Classification of violence

No.	Fault lines	Direct violence	Structural violence
[1]	Nature	slaughter of 'beasts, savages, wilderness'	depletion pollution
[2]	Gender	killing women: abortion, infanticide, witch-burning	patriarchy as prison of women, putting them 'in their place'
[3]	Generation	<i>Privileging</i> abortion euthanasia	<i>middle-aged</i> schools as ghetto 'homes' as ghetto
[4]	Deviance —criminal —mental —somatic	<i>Controlling dangerous persons</i> capital punishment euthanasia euthanasia	institution institution institution
[5]	Race	<i>Controlling dangerous races</i> eradication slavery	colonialism slavery
[6]	Class —military —economic —political —cultural	<i>Controlling dangerous classes</i> elimination	exploitation-body repression-mind alienation-spirit
[7]	Nation Culture Ideology	'genocide' as narrowly defined	the state as a prison of nations run by 'majority'
[8]	State Country Territory	war (killing for food, sacrifice, conquest)	imperialism isolating 'pariah' states

then move into Pacific American African spaces, picking up a Polynesian, an Amerindian, and an African tradition, ending south of Europe.

1. *Europe: Pax and Eirene—The Roman/Greek and Modern Traditions*

Peace can be interpreted narrowly as *absentia belli*, the absence of organized violence between groups defined by the fault lines. International or external peace is the absence of external wars: intercountry, interstate, or international (in the sense of intercultural). Social or internal peace is the absence of internal wars: national, racial, class, or ideological groups challenging central governance or each other. This concept is carried by the Roman *pax*, related to pact, as in *pacta sunt servanda*, 'treaties must be observed.' Peace as a contractual, mutually agreed relation is the source of Western international law.

Another Roman legacy, *si vis pacem, para bellum*, 'if you want peace prepare for war,' is the source of Western military peace theory. Peace is obtained by the balance of power, deterring the aggressor at home with defensive defense, and abroad with offensive

defense. Offensive offense (attack/aggression) and defensive offense (pre-emptive warfare) are not peace concepts.

Aggression is controlled from above by pacts—the Roman Empire was capable of enforcing such pacts—and/or by the balance of power. A better word for this kind of peace is security. And there is a basic dilemma: the military capability used to deter can also be used to attack, even if the motivation is defensive. The result can be an arms race, a cold war, or even an actual war.

A basic problem with the Roman *pax* is its insensitivity to flagrant injustice and inequality, the Roman Empire itself being an example. The Greek *eirene* is closer to 'peace with justice': absence of direct and structural violence, among Greeks. But which part has priority? What if they think justice can only be obtained through war? That idea was picked up by the Marxist tradition as class war, national and international, legitimized as necessary and sufficient to obtain a just, socialist society. The Roman thinking led to the liberal tradition, tolerant of enormous inequalities, nationally and internationally, but strongly against war, both internally and externally. And Roman warfare was picked up by the conservative tradition, extolling still more inequality through

wars, provided they could be won, and even through empire-building. In the year 2000 these views still prevail.

2. *Europe: Agape and Bellum Iustum: The Christian Traditions*

The three main divisions of Christianity (Orthodoxy/Roman Catholicism/Protestantism) and the many smaller sects had Paradise and Hell as archetypes that became models for peace and war, making peace remote and static, and war a highly dynamic hell on earth. Peace is seen as ordained by a God whose law is the only valid law, and valid for all of humanity. But who is God, and how does he relate to human beings in search of peace?

A theological distinction is very useful here, between God as immanent, inside us, making us godlike, sacred, and God as transcendent, above us, saving, choosing some persons and peoples, rejecting and condemning others. We may even talk about soft and hard Christianity, depending on which God-concept is picked up, in what proportion. They do not exclude each other.

Agape (Greek for 'love') can be used as a name for the peace of a soft Christianity based on an immanent conception of God. There is God's love for humankind, through Jesus Christ; the human love for God; and the love of one's fellow beings as being God-loved. The Lord's Supper and the Eucharist are close to this concept: a community of humans, God-enlightened, *in* God. The face-to-face *corpus mysticum* is based on an identity with others so strong that there is a limit to the number of members. This may be a reason why very egalitarian, interactive, direct peace concepts spring out of smaller Christian sects, like the Quakers and the Mennonites.

Then there is the transcendent God, conceived as some male person residing above our planet, and his relation to nonbelievers, pagans, and worse still, to the heretics who have rejected God. This is where hard Christianity enters, administering Hell and torture (the Inquisition) and Holy War to the heretics.

As some kind of peace concept it takes the form of *bellum iustum*, in the Augustine-Aquinas just war tradition:

- (a) Wars must be waged by a lawful authority.
- (b) Wars must be waged for a just cause, to correct injustice.
- (c) Wars must be waged with the right intention, not vengefully.
- (d) Wars must be waged as a last resort and with prospects of success.
- (e) Wars must be waged with proportionality and minimum force.
- (f) Wars must be waged only against combatants.

The first five are *ius ad bellum*; the last two are *ius in bello*.

This can be seen as an effort to limit war even if accepting war as the last resort. But there is no nonviolent alternative, and it may be used to attack any kind of injustice however defined. In addition, it is not biblical but derives from St. Augustine and St. Thomas Aquinas. But this cost-benefit thinking is still with us.

3. *West Asia: Shalom/Sala'am—The Judaic and Islamic Traditions*

Looking at some famous quotes from the basic texts (see Table 2, Christianity is included as a family member for comparison) one conclusion may be that ambiguity is the message. It is neither unconditional peace, nor unconditional war. It is peace under certain conditions and war under certain conditions. The problem is to spell out those conditions. One reading of the Judaic *shalom* and the Arab *sala'am* is peace with justice. Without justice, no peace; hence war for justice is legitimate. The contradiction is mirrored in the quotes shown in Table 2.

If we define justice as absence of structural violence whereby people, nations, and states are repressed, exploited, alienated, but not by an actor, then this may lead to *bellum iustum* as injustice abounds. *Jihad*, however, translates as 'exertion' for the faith. Defending the faith by violence, against Crusades, Zionism, communism, is the fourth stage of *Jihad*.

4. *South Asia: Shanti and Ahimsa—The Hindu/Jainist/Buddhist Traditions*

There is a trend in all three faiths toward unconditional peace by *ahimsa*, nonviolence. The major carrier of this message of all times, Mohandas K. Gandhi (1869–1948) used the formula 'There is no way to peace, peace is the way.' This is a strong stand, ruling out violence as immoral and unproductive. The struggle against violence, direct or structural, is by nonviolence. And, as becomes clear from Gandhi's adulation of the small social unit, the village, peace in the sense of absence of direct violence, cannot be built top-down by heavy international and national hierarchies, in the *pax* and Hobbesian traditions.

This, in turn, is related to *shanti*, inner peace. *Ahimsa* has *shanti* as a necessary condition: with no inner peace, no nonviolence. 'Unprocessed traumas' will be acted out aggressively. If nonviolence does not lead to change of heart in the other, it is for lack of change of heart in self. Nonviolence then turns into self-purification, practiced in the little community of believers, the *sangha*, which is like a monastery.

Gandhi left behind a theory and practice of *satyagraha*, clinging to truth as he called it. Look at the list of nonviolent action: to play a major role in delivering the nonwhite world from white colonialism,

Table 2
Hard and soft peace: quotations from Judaism, Christianity, and Islam

	Judaism	Christianity	Islam
Soft peace	He will decide the disputes of the nations and settle many a people's case ... till swords are beaten into plough-shares and spears into pruninghooks. No nation draws the sword against another. (Isaiah 2:4)	How blest are the peacemakers. God shall call them his sons. (Matt. 5:9)	And whoever saved a human life, should be regarded as though he had saved all mankind. (Qur'an 5:32)
Hard peace	For in the cities within the boundaries of the Promised Land you are to save no one; destroy every living thing. (Deut. 21:16)	Don't imagine that I came to bring peace to the earth. No, rather, a sword. (Matt. 10:34)	Fight for the sake of Allah those that fight against you but do not attack them first. (Qur'an 2:190)

and the white world from its own Cold War, leaving no thirst for bloody revenge behind, is no minor achievement. That gift comes out of South Asia, not the West. The contribution of the West seems to a large extent to have been to create the problems. The burden of proof is on those who teach peace by violence. To assert 'nonviolence does not work' is uninformed, given the amazing successes in the second half of the twentieth century:

(a) the liberation of arrested Jews in Berlin, February 1943

(b) Gandhi's *swaraj* campaign in India; Independence from 1947

(c) Martin Luther King Jr.'s campaign in the US South from 1956

(d) the anti-Vietnam war movement, inside and outside Vietnam

(e) the Buenos Aires Plaza de Mayo mothers against the military

(f) the 'People's Power' movement in the Philippines, 1986

(g) the Children's Power movement in South Africa, from 1986

(h) the *intifada* movement in Occupied Palestine, from 1987, in the beginning mostly nonviolent

(i) the democracy movement Beijing, spring 1989

(j) the Solidarity/DDR movements which ended the Cold War.

harmony would be not only 'absence of violence,' but 'absence of conflict.' The task of conflict resolution has already been carried out. Indications of conflict are swept under the carpet, and the person articulating conflict is frozen out of harmonious society, or prevented from expressing such views.

Take the metaphor of Chinese boxes, or in Russia the *matrushka* dolls, with one box or doll inside the other and so on, till they become extremely small. They all look alike. In modern fractal/chaos theory they talk about 'self-similarity' as something stabilizing. The basic East Asian point is that harmony is produced not by a particular structure, be that a pyramid or wheel or whatever, but by the same structure repeated at the personal, social, and world levels, within and between.

In *Tao Te Ching* we find an example: small, detached countries: 'Though they have armor and weapons nobody displays them—they leave each other in peace while they grow old and die' (No. 80). A modern version would be domestic and global democracy.

6. *Pacific, America, Africa—Ho'o ponopono, Peace Pipe, and Shir*

The following are three examples of peace as non-violent conflict resolution.

5. *East Asia: Ho p'ing/Heiwa—The Chinese/Japanese Traditions*

The standard translation of *ho p'ing* (Chinese) and *heiwa* (Japanese) is 'harmony.' And one reading of

6.2 *Ho'o ponopono—The Polynesian Conflict Resolution Circle*

Ho'o ponopono (setting straight) is a method of conflict resolution that brings together around a table per-

EUROPE, secular: <u>Balance of power</u> <u>Rule of Man, Law</u>		
EUROPE, Christian: Soft: <u>agape</u> Hard: <u>bellum iustum</u>		
WEST ASIA: <u>shalom, Sala'am</u> Soft: the Wheel Hard: the Pyramid		
SOUTH ASIA: <u>The sangha wheel</u> <u>Shanti/Ahimsa</u> both soft

Figure 1

Geometric images of peace

petrator, victim, family members, neighbors, friends, and others, with a moderator, the 'wise man,' not from families or neighbors. The process of resolution has four stages.

Everyone is encouraged sincerely to present their version of why it happened, how, and what would be the appropriate reaction, and everybody accepts some part of the responsibility. Sincere apologies are then offered and accepted; forgiveness is demanded and offered. An action program is defined for everybody according to the principle of shared responsibility. And in the end the record of what happened (but not of what has to be done) is then burnt, symbolizing the end of the incident, and the construction of a new relation among all of them.

6.3 The Peace Pipe—The Cheyenne Conflict Resolution Symbol

With the Cheyenne, a zone of peace is created at the top of society, with the peace chiefs being models of

nonviolence to be emulated by the rest. They were not to engage in any quarrels within the tribe regardless of whether their families or children were involved. They were not to engage themselves in any force or violence, even if their son was killed right in front of their tepee. You are to do nothing but take your pipe and smoke. Being a chief becomes a way of life, and the chief's home a sanctuary where others can be safe. The chiefs mediate disputes and don't take sides. Ritual, like smoking the peace pipe together, makes it possible to think with one mind, one heart. Everyone has a right to talk, nobody is interrupted, the talk continues till the end.

6.4 Shir—The Somalian Conflict Resolution Market

A traditional conflict resolution structure that brings together all the mature men in the clans involved in a conflict. Women, children and young hot-blooded warriors are excluded. Men lounge under the thorn trees during the hot, dry day. They chat and drink tea.

At some point, things will jell. The various pieces that make up the main issue for which the *shir* was called will fall into place because a social climate conducive to a solution will have slowly emerged. The result will be proper peace—a peace felt from the inside.

Conflict resolution has here been hitched on to one of the oldest institutions in the history of human beings: the market. The market is based on exchange for mutual benefit: I give, you give (*do ut des*, I give so that you give), and some principle of equal exchange, (*quid pro quo*).

7. Peace as Geometry

Five geometric archetypes for peace are shown in Figure 1: the vertical, big pyramid for the hierarchic rule from above, of human beings or of law; the wheel for the smaller, tight, equal exchange; the symmetry—like the garden of Versailles—for the balance of power; the sun for the nonviolence radiating from inner peace; and the Chinese boxes of harmony based on self-similarity, from micro to macro levels.

Different kinds of peace can also be expressed in terms better known from the history of diplomacy, focusing on interstate and international peace: the Napoleonic peace forged by a prince/lawmaker; the silent peace brought about by groups of ordinary humans, or countries; the Nixon–Brezhnev peace negotiated at a bilateral summit; the Gandhian peace as process, not only outcome; the anonymous peace as built-in harmony. All of these are used for conflict resolution. How conflict is handled is the best peace indicator.

8. Approaches To Peace

Each society, community, family, and person has ways of being peaceful by peaceful means, but they also often have ways of being violent, summarized in their cultures. A major approach to peace concerns is to tilt the cultural balance in favor of peace, letting peace cultures be the dominant cultures. Then, using the survey of peace cultures and the peace as geometry approach we have five ideas in addition to peace culture.

The two Europes and West Asia have one idea in common: the hierarchy, the pyramid. Essentially this is peace from above, whether from a big power, a combination of big powers, or from some central authority. The current term is ‘global governance,’ based on global architecture. Regional versions may produce regional peace among members, excluding nonmembers. The counterpoint to the pyramid, the wheel, found in five cultural spaces, expresses the ideas of peace from below, small is beautiful, inspiring the search for alternative peace structures. Then comes

the *shanti–ahimsa* combination from South Asia: the source of peace is inside you, its expression is non-violence, which makes war abolition a realistic utopia. And we pick up the idea of conflict transformation, with East Asian harmony as outcome, *ho’o ponopono*, peace pipe, and *shir* as examples of processes.

The six approaches divide into two groups: global governance, war abolition, and conflict transformation being more familiar; nonviolence, peace structures, and peace cultures unfamiliar and challenging. Peace in the complex, highly interconnected world of the twenty-first century, bringing conflict parties very close to each other, will depend on the ability to draw upon all six—not easy given that they hail from different parts of the world.

Peace and Nonviolence: Anthropological Aspects

1. Definitions

The phrase 'peace studies' refers generically to studies of the dynamics of 'peace,' and specifically to the natural history of 'peaceable' or 'nonviolent' peoples. The two main foci, which overlap significantly, are (a) the analysis of particular conflict-resolution techniques, and (b) the holistic study of peaceable peoples.

1.1 Problems of Definition

The terms 'peace' and 'nonviolence' are relative, not absolute, referring to adaptations which are often transitory rather than to essential natures which persist indefinitely. Although researchers use the words 'nonviolence' and 'peace' as rough synonyms, the former creates methodological problems. How to observe and analyse the absence of violence? It might be useful to reserve this term for ideals such as Gandhi's *ahimsa* or related techniques such as the nonviolent protest of the 1970s 'Peace Movement' of Europe and America, from which peace studies arose and borrowed the term.

Likewise, in most Indo-European languages 'peace' is a null category. When you have no violence, you have peace. Linguistically, violence is the norm. Peaceable peoples are 'nonviolent' (Ashley Montagu) or 'low-conflict' (Marc Ross). It is difficult for students of peace to avoid drifting into the null construction of peace which pervades the cultures within which they live their lives.

By contrast, Semai, a peaceable Malaysian people, use the term *slamad* to refer to a condition of security and serenity which they nurture with the same zeal that Indo-Europeans pursue wealth and happiness. In Semai construals, *slamad* is normal, 'non-*slamad*' the null category. Recent peace studies stress the distinction between 'negative peace' (refraining from violence out of fear) and 'positive peace' (maintaining *slamad* out of love of peace). In this construction, both forms of peace are activities rather than absences of activity, involving conscious and unconscious 'peace-making' rather than voids. Defeat involves an agent's act of surrender as well as another agent's act of conquest. 'Peacemaking' is thus the category of behaviors and social patterns on which peace studies focus.

2. Why Not Study Peace?

2.1 The Ubiquity of Peace

Any survey of the literature will uncover hundreds of articles on violence for every one on peace. Yet the

most violent people spend most of their time in humdrum peaceful activities: Eating, sleeping, talking, daydreaming, scratching, and otherwise doing no harm. Most people in the most violent societies, even in wartime, spend their days in peaceful pursuits (Nordstrom 1997). The life of a soldier in wartime involves more hours of boredom than moments of terror.

No wonder. Violence hurts, and individuals dislike getting hurt. The possibility of counter-violence makes violence self-limiting in a way that peace is not. People prefer hurting those who, for whatever reason, cannot retaliate. Domestic violence is probably the commonest form of violence cross-culturally, simply because perpetrators are relatively safe from retaliation (Gelles and Straus 1988). Even then, when local values justify violence, the way human perpetrators obfuscate their actions by appealing to peace ideology reveals their uneasiness with violence: they are 'maintaining law-and-order,' 'keeping the peace,' 'disciplining students,' or 'teaching them a lesson.'

In evolutionary terms, that makes sense. Other things being equal, organisms that avoid serious fighting with peers are more likely to survive long enough to produce fertile offspring than those that usually win fights but risk counter-violence; i.e., peaceful organisms are fitter. Moreover, violence disrupts cooperative activities that enhance the fitness of social organisms like humans. Such disruption is a common theme in nonWestern peoples' reconciliation ceremonies: if we fight, who will help to harvest the crops? Fear of disruptive violence rationalizes human rulers' stamping out or severely limiting freelance violence, and monopolizing violence for themselves and their state. As a result, throughout human history peace prevails, in most places, most of the time. Peace is normal and normative. Violence is abnormal and disruptive.

2.2 Reasons Not to Study Peace

So why does peace get so little attention, even from social scientists? One reason is the definition of peace as an absence, discussed above. There seem to be several others. One probable reason is evolutionary: Violence threatens fitness. Successful organisms attend to threats. Violence is a problem; peace is unproblematic. So peace remains in the background, and violence is dramatic. Unsurprisingly, the most popular account of paleoanthropic violence is by a dramatist, not a paleoanthropologist, primatologist or prehistorian (Ardrey 1961). The very prevalence of peace makes violence salient: The exception, 'man bites dog,' makes news. Normal conditions do not.

Answers to the question of how to live in peace have potential political consequences, which might affect the lives not only of this generation but of generations to come. In the 1990s, over 2 million children died in wars, 6 million were seriously injured or permanently

disabled, a million orphaned, and 12 million made homeless. Children are the main victims of enslavement and domestic violence.

Awareness that research may be consequential can make it teleological, arriving at conclusions which reflect researchers' political predilections. Hobbes, an early student of violence and peace, deliberately excluded empirical considerations from his work, relying instead on an a priori method which he felt derived from Euclidian geometry, and concluding that the political despotism of his time was a counter-violence needed to control the freelance violence which would otherwise ruin human life. Similarly, peace studies evolved from New Left political activism in the 1970s. A large number of peace theorists are pacifists or members of quietist religious groups like Quakers or Mennonites. Many are explicitly political, arguing that, since they feel peace requires respect for human rights and social justice, anthropology should espouse such causes. Pedagogy is a central concern.

The resulting atmosphere may alienate students who hold traditional social science notions of 'objectivity.' Moreover, this sort of partisanship generates equally political responses by students of violence and others for whom, as Max Weber warned might happen, social science is the handmaiden of the Establishment and the social controls that maintain it in power. Social justice, say the reformers, will produce (positive) peace. No, say the establishmentarians, sometimes marching under the banner of objective social science, you need the hangman and the Bomb (negative peace).

Such politicization makes researching these topics difficult: For example, anthropologists have been reluctant to undertake (and funding agencies to finance) studies on domestic abuse among indigenous peoples, at least partly because the hegemonic liberal ideology frames indigenous peoples as simple and peaceful, and representing them otherwise might exacerbate the difficulties they already face in finding allies among more powerful peoples. In rebuttal, opponents seem to be reviving the nineteenth-century hegemonic representation of indigenous peoples as savage and violent, an equally political representation (e.g., Keeley 1996).

It may be impossible and even undesirable to eliminate political concerns from research that is so 'sensitive.' It would be helpful to make them explicit, as students of peace traditionally do. But scholars may be unaware of the teleological concerns that bias their results. Even researchers, after all, swim in their own culture like fish, mostly unaware of how the medium that supports them also affects how they perceive the world.

A cognate difficulty is that discussions of peaceability often degenerate into speculations about 'human nature,' a Platonic essentialist concept which serves more to terminate research than to stimulate it (but cf. Boehm 2000). If people are 'naturally' violent,

violence needs no explanation; if 'naturally' peaceable, peace requires no further examination. Recent studies such as Keeley's (1996) suggest that violence has been part of human societies since early in prehistory. There may be no society in which violence has never occurred. By the same token, there is no society in which peace never occurs, in which the general rule is a Hobbesian war of each against all; and no period in prehistory or history at which no one lived in peace. One of the most interesting studies of war describes how, in the midst of all-pervasive violence, people continue doggedly to construct peace (Nordstrom 1997). The half-empty glass is half-full (Boehm 2000), and the decision on the question of human nature is more likely to reflect the political sensibilities of the researcher than the empirical data.

3. Styles in the Study of Peace

The two main foci of peace studies reflect the dichotomy between positive and negative notions of peace. Although the sketch given in the previous section of 'establishmentarians' versus 'reformers' is a heuristic oversimplification of impulses which overlap and may coexist within the same person, nevertheless it is not completely inaccurate to see the establishmentarian impulse in the first focus and the reformist in the second.

3.1 Conflict Resolution Studies

The first subfield is, at least implicitly, instrumental or 'applied' anthropology, reflecting governmental interests in international diplomacy and administrative measures to reduce freelance violence, e.g., in the school system. It comprises 'conflict-resolution' or 'mediation' studies of the sort emphasized by the journal *Peace and Conflict Studies*—www.gmu.edu/academic/pcs. In the United States, George Mason University is a center for such studies. Since World War II, conflict resolution studies in anthropology have grown in tandem with their growth in psychology, sociology, and political science. This upsurge seems to be connected with the rise of UN 'peace-keeping' efforts and interventions by the USA and Western Europe in overseas conflicts. More recently, the perceived rise of violence in the USA has led to funding of 'violence prevention programs,' for example, by the Justice Department. Most such programs stress peaceful conflict resolution, sometimes purportedly modeled on 'primitive customs.'

Most conflict resolution theory is a subset of game theory models, in which participants try to maximize benefits to themselves, and minimize their losses. The ideal solution is 'win-win,' in which for each participant the sum of the benefits outweighs the sum of the losses. Ideally, participants arrive at a 'rational'

resolution through reasonable (ideally numerate) discussion, perhaps with the help of mediators from outside, trusted by both parties, experienced in mediation, and dedicated to resolving conflicts peacefully. The 'anthropological' character of conflict resolution studies comes mostly from the attempt, in the face of skepticism from other disciplines, to deploy the concept of culture, and from the occasional choice of 'tribal' peoples as subjects. In general, however, the concerns and analytical techniques (e.g., cost-benefit analysis) are indistinguishable from those of the other social sciences.

Of course, as 'conflict theorists' have insisted since Georg Simmel, conflict is ubiquitous and need not produce violence. Conversely, conflict resolution is neither necessary nor sufficient to produce peace (Fry and Bjorkqvist 1997). Many nonWestern peoples traditionally held interminable meetings explicitly to resolve conflict. During these meetings, everyone got to speak at length until participants were physically and emotionally exhausted, and no one had any unvoiced opinions. The conflict might remain, but angry emotions dissipated and the conferees could reconcile or agree to differ.

Another practical limitation is that most conflict resolution techniques require that participants be equals or equally subject to coercion by a power greater than they are. But, as cost-benefit analysts of domestic violence point out, violence is most likely to occur when unpleasant consequences for the perpetrator are negligible, i.e., when the parties are unequal (Gelles and Straus 1988). Thucydides records a conflict resolution conference between Athenians and Melians. Since the more numerous and better-armed Athenians could (and later did) overwhelm the Melians, the Melian conference 'failed.'

The corollary is that egalitarian societies tend to be peaceable, and peaceable ones tend to be egalitarian (Fry 1999); between nations, 'mutual deterrence' depends on perceived equality. Perhaps social justice in the form of felt equality is also important. Thus, although conflict resolution theorists tend to dismiss other tactics for preventing violence as unreliable (Fry and Bjorkqvist 1997), conflict resolution techniques are most likely to succeed when least likely to be necessary.

3.2 *Peace Studies*

Peace studies are more ethnographic, less technical and more value-laden, finding expression in, for example, *Human Peace and Human Rights*, journal of the Commission on the Study of Peace and Human Rights of the International Union of Anthropological and Ethnological Sciences—rar@syr.edu. Syracuse University is a center for such studies as well as for conflict resolution studies in the USA. This research rests on the empirical observation that conflicts among

some aggregations of people are less likely to erupt into violence than among others. One reason for such peace is a value system that promotes negative peace by abhorring violence (e.g., as stupid, scary, or self-destructive) and promotes positive peace or *slamad*, a value system somewhat like that of the 1970s 'Peace Movement' which inspired peace studies.

But that movement itself grew from the Vietnam War. Peace tends to be valued particularly by people who know violence firsthand. Peaceable values may maintain peace, in the short run, but they gain strength from the threat of violence (DeBenedetti 1978, Dentan in Silverberg and Gray 1992, in Sponsel and Gregor 1994, Nordstrom 1997). And one reason for war is that outsiders threaten *slamad*. In short, attributing peace only to peaceful values is as simplistic as attributing violence to 'innate aggression.' The stipulated variables are insufficient to produce the observed results.

The ethnology of peaceable peoples reveals how complicated is 'peace.' Documentation exists on a fairly large number of relatively peaceable societies, including traditional ethnic groups (e.g., Dentan in Silverberg and Gray 1992, Fry 1999, Howell and Willis 1989), cenobitic pacifists like the Amish or Hutterites, and other voluntary associations such as the Friends, the Rainbow Family, or Alcoholics Anonymous (AA) (1994). Most have formal and informal conflict-resolution techniques, the latter derived from those characteristic of the species as a whole (Boehm 2000, de Waal 1989). Most lack the in-group economic or political hierarchies which impede consensual conflict-resolution, although many are enclaves in hierarchical societies against whom they must maintain identity barriers.

Peaceable values are conducive to peace. Many peaceable peoples like peace better and violence less than more violent peoples do. But many, for example, the Amish and Mbuti, beat children severely. Others, such as the Semai, fantasize warfare against their oppressors, or boast, like the AA, that members can stand up to the challenges of warfare when their country calls. Generally, in-group peace seems more valued than peace with outsiders. And, as the ubiquity of peace may indicate, most people prefer peace to violence except under exceptional circumstances.

'Negative peace' based on fear of consequences seems more salient than 'positive peace' based on idealist values. Many peaceable peoples, particularly cenobitic pacifists, are patriarchal and physically punish disobedience by children. Oppressive regimes can also diminish freelance violence by retaliatory violence such as incarceration, mutilation, or capital punishment.

Avoiding others is yet another way of peacemaking. Cross-culturally, inevitable structural conflicts, such as that between a man and his in-laws over who benefits from his wife's services, may result in formalized respect/avoidance relationships in which one or

the other party expresses extreme deference to, or even avoids social contact with, the other. Avoiding a person with whom one is angry is an effective passive-aggressive communication of the anger and dramatizes the threat of withdrawing cooperation. Many peaceable societies of Southeast Asia arose in the context of a political economy based on slavery and coerced trade, in which the best way to avoid enslavement was to flee. Catholics and Protestants in Northern Ireland, like 'blacks' and 'whites' in the USA, tried less successfully to minimize violence by minimizing mutual contact.

Another way of dealing with inherent conflict is to transform physical violence into 'harmless' symbolic violence. To some extent, sports in the Western world do provide the 'moral equivalent of war' that William James imagined. The 'joking relationships' that occur in many societies allow people to express anxiety and frustration about possible conflicts, especially involving sex, by hostile words and deeds which local ideology defines as 'not serious.' This technique is unreliable: fans battle each other and 'locker room humor' can erupt into violence.

3.3 The Future of Peace Studies

What is needed is meticulous field studies of peoples who seem better at peacemaking than others. Such studies require avoiding essentialist notions of peaceability as a psychosocial deficiency, the inability to be violent under any circumstances. Rethinking definitions of peace and violence seems appropriate (e.g., Dentan 2000). If peaceability is an adaptation rather than an essence or changeless value, then changing circumstances should affect peaceability, so that such studies must take account of history in order to discover what variables are important. Perhaps the most promising future studies are those which make detailed comparisons between (a) peacemaking among specific human groups and among specific other primates (e.g., Cords and Killen 1998), or (b) 'controlled comparisons' between particular peaceable peoples and otherwise similar but more violent peoples, e.g. the studies of peaceable and violent Zapotec towns by O'Neill and Fry (see Fry 1999); the Robarcheks' planned book-length expansion of their chapter on peaceable and violent tropical rainforest swiddeners, the Semai and Waorani (Robarchek and Robarchek 1992); the comparison of peaceable and violent Chicago neighborhoods by Sampson et al. (1997).

3.4 The Use of Peace Studies

Improving conflict resolution techniques is of obvious importance. Are any lessons from peaceable societies of possible use to other peoples? The great student of

primate conflict resolution, Frans de Waal dismisses peaceable human groups as a 'few gentle, nonmartial human societies that have managed to survive in remote corners of the world' (1989, p. 4). But many cruel martial human societies have also perished, because their cruelty and violence was as unsustainable as is peaceability as de Waal implies. The British poet Shelley's poem *Ozymandias* says it best: There is an immense broken statue in the poem, on whose base are the words: 'My name is Ozymandias, King of Kings. Look on my works, ye mighty, and despair!' All around the statue, as far as the eye can see, the desert lies unbroken. Scientists must not let the drama of violent conquest obscure the fact that organisms and societies often survive better by eschewing, preventing, or avoiding violent conflict than by engaging in it. As a long-term adaptation, neither peaceability nor violence is necessarily or essentially 'good' for survival; in the short term, either may work, depending on the circumstances. That is why peaceable people like the Semai may stop being peaceable, and violent people like the Waorani may turn to peace. Both fight and flight are active adaptations, which couple with caring for children and forming alliances ('tend and befriend') as human responses to environmental stress. The dynamics of these adaptations need the same careful study as any other ecological adaptation.

Peace Movements

‘Peace Movements’ may be used in two ways. On the one hand, a peace movement is a specific coalition of peace organizations that, together with elements of the public, seek to remove a threat of war or to create institutions and cultures that obviate recourse to violence. On the other, it is the organizational infrastructure to do so. Usage is usually clarified by context. Peace organization constituencies are people with shared commitment to common values and traditions, like religious pacifism, or to a program such as world federalism. Such groups form coalitions in order to enlist public support in response to salient issues. If the issue is war or a specific war threat, peace coalitions take the form of antiwar movements. In nearly 200 years of organized peace effort, specific peace movements have affected national policies, international institutions, and popular attitudes. Taken as a whole, they can be viewed as a single, evolving, and increasingly transnational social movement that has interacted with formal analyses of war, peace, and social movements. The conceptualization of peace movements has resulted from the dialectical interaction of the movement’s self-reflection on its experience and subsequent scholarly analysis.

1. Growth and Self-definition, 1815–1939

In western civilization peace has been understood mainly as the absence of war (Chatfield and Ilukhina 1994). Given war’s existence, there were two main ethical alternatives: a dominant ‘just war’ tradition

that legitimated organized violence under specific conditions, and a minority tradition of individual Christian nonresistance that rejected violence altogether. There was no sustained tradition of organized popular effort to check interstate warfare.

That was the situation when small peace societies were formed in the United States and the United Kingdom (1815) by a few local nonconformist Protestants who denounced warfare. In the next 100 years civic associations for societal change became common in western societies, providing the context in which peace organizations grew and defined themselves.

1.1 Early Internationalism

Peace constituencies broadened within an educated elite. British and American leaders solicited support on the Continent, where peace advocates tended to be secular intellectuals and where Richard Cobden’s program of peace through free trade became very influential (Cooper 1991). During the 1840s leaders on both sides of the Atlantic promoted international arbitration. A few went further, a congress of nations, an international court, and even a united Europe. Then, in mid-century, peace advocates were shaken by wars in the Crimea, Germany, Italy, and America.

Gradually the movement was rebuilt in the latter third of the century. American and European leaders promoted treaties of arbitration, forming a program-oriented peace movement propelled by a bias for *internationalism*—the conviction that warfare is irredeemable and that statesmen could render it obsolete by breaking down barriers, building up international law, and seeking practical mutual interests beyond conflicts. The American Peace Society (1928) and the *Ligue internationale et permanente de la paix* (Paris 1863) popularized this approach. The *Ligue internationale de la paix et de la liberté* (Geneva, 1867), however, pressed the view that peace could be secured only by political justice among self-determining, democratic peoples. Concurrently, the First and Second (socialist) Internationals held that peace was contingent upon economic justice—the overthrow of capitalism. In practice, though, as socialists entered the political mainstream they supported programs of arbitration, arms limitation, and anticolonialism—peace as liberal internationalism, which was christened ‘*pacifism*’ (Cooper 1991, p. 237, n. 1).

1.2 An Internationalist Peace Establishment

The movement for liberal internationalism obtained strong leverage from the First Hague Conference in 1899, when the great powers endorsed pacific alternatives to war. By then approximately 100 national and

regional societies were linked by an office in Berne, Switzerland (International Peace Bureau, 1891). Within another decade there emerged (mainly in America) several well-funded associations, notably the Carnegie Endowment for International Peace. They constituted a kind of *peace establishment*, an elite of business, legal, and governmental leaders who promoted the arbitration process. In World War I most of these internationalists proved to be patriots first. The word 'pacifism' became narrowed, especially in Anglo-American usage, to mean the absolute, individual rejection of war. Wartime peace advocates were repressed.

1.3 Peace and Internationalism Redefined

The war that shaped the twentieth-century world reshaped peace movements, which emerged more transnational and politically activist than before.

A few internationalists concluded that peace required some constraints on national sovereignty, that war is irrational, and peace requires 'a systematic effort to institutionalize managerial controls over the fragile interdependence of modern industrial civilization' (DeBenedetti 1978, p. 8). Such *liberal internationalism* was institutionalized in the League of Nations and its efforts for arms control, but also in an international network of civic League of Nations Associations. From wartime pacifism there emerged other transnational associations: the Women's International League for Peace and Freedom (1919), the pacifist International Fellowship of Reconciliation (1919), the linked British and US Quaker service committees (by 1917), and the International War Resisters League (1921).

At the same time, a new constituency of political reformers carried their campaign against corporate evil and systemic injustice into the peace movement. Women fresh from suffrage campaigns, for example, revitalized earlier analyses of war as a problem of social structure. Especially in England and America peace movements acquired a constituency of middle-class women and men who linked peace and justice and for whom peace movements were social change agents.

Following the war these activists informed and mobilized public opinion, engaging in the politics of pressure groups to challenge military spending and influence foreign policy. Peace advocates were vocal also in Germany and France, where they had been suppressed in wartime, and socialists throughout Europe took up the peace cause. Unfortunately, differences over priorities and policy hobbled peace efforts throughout the 1920s. The American movement was a sad case in point: groups promoting the League of Nations, the outlawry of war, disarmament, peace education, and international law failed to

coalesce. Early in the next decade peace advocates organized internationally to support the League's 1932 disarmament conference, but in the face of aggression they soon realigned as rival supporters or opponents of collective security. No cohesive peace movement could be discerned among the bitter contests waged for public opinion.

2. External Assessment: Early Histories

The self-reflection of peace advocates on their experience affected the formal studies that began in the early 1930s with a few general histories. British scholar A. C. F. Beales, for example, interpreted *The History of Peace* (1931) optimistically in light of alternative programs broached when he wrote. A half decade later, Merle Curti's *Peace or War: The American Struggle 1636–1936* (1936) more soberly emphasized the gap between pacific ideals and the realities on which warfare is grounded (notably economic factors). Pacifist Devere Allen's earlier *The Fight for Peace* (1930) interpreted the historic American movement against his own norm of nonviolent activism and war resistance.

3. Nonviolence

Allen's book itself was part of the historic development of secular pacifism into an ideology of proactive, nonviolent change. That shift made the early *Satyagraha* campaigns of Mohandas Gandhi in India important to western contemporaries, and later to American civil rights leaders experimenting with non-violent direct action and civil disobedience. Early sociological interpretations of *Satyagraha* were absorbed into the pacifist literature on nonviolence by the 1930s. Conversely, later experiments with the method in civil rights and antiwar campaigns expanded scholarly analyses of it. Thus nonviolent direct action developed dialectically along practical and theoretical lines (see Powers and Vogeley 1997).

Moreover, the use of nonviolence in the struggle for justice applied the concept of peace as change without violence. Understanding peace as nonviolent social change for justice, rather than only as the absence of war, underlies the now common analytical distinction between positive and negative peace.

4. Cold War Mobilizations

During World War II, a fresh peace coalition formed around the United Nations (UN) ideal. It was grounded in liberal internationalism and it generated public support for a UN organization. Movement-

related nongovernmental organizations (NGOs) were responsible for including human rights under UN purview and for gaining consultative status in the organization. Even world federalism elicited much public support until it, along with initial efforts to contain nuclear arms, was undercut by the Cold War. By 1950 peace and liberal internationalism were victims of global polarization. The older peace organizations remained intact, but they lacked a salient issue around which to build any coalition.

4.1 *The Nuclear Test Ban Movement*

In the mid-1950s the issue of testing thermonuclear weapons on a massive scale aroused a fresh, transnational peace movement. It was grassroots based and was well organized on national levels. It made use of print and film media, mass demonstrations like the annual Aldermaston marches in England, political lobbying, and nonviolent civil disobedience such as sailing into test zones. The movement contributed significantly to a temporary moratorium on testing and to the 1963 Partial Test Ban Treaty.

4.2 *The Antiwar Movement of the Vietnam War Era*

Then the global movement lost coherence. The nuclear threat seemed to diminish and activists faced other issues, most dramatically the US war in Vietnam, which provoked worldwide opposition. The center of the storm was in the United States, where political radicals, pacifists, and liberal internationalists aligned in a loose, tenuous coalition. The whole repertoire of activism was employed: popular education, political pressure and lobbying, electoral politics, and street demonstrations. Although identified with radical counterculture in public opinion, opposition to the war increasingly enlisted mainstream activists and infused congressional politics. Extrication from Vietnam coincided with an exhausted peace movement and apparent détente in the Cold War.

Détente collapsed at the end of the 1970s. In response to a heightened nuclear arms threat, a new peace coalition arose that was transnational, massive, grassroots based, and aligned with environmentalists (most fully the Greens in Germany). Internationally, movement cooperation focused on UN disarmament negotiations, but it was ineffective owing to rival political agendas. Nonetheless, the movement enlisted broad public support, which it focused on the threat of nuclear war, and it reinforced arms control negotiations. It also broadened the political base in several countries and stimulated movement contacts with counterparts in the Soviet bloc.

Meanwhile, an informal coalition of peace and human rights activists in Central and North America effectively stymied overt US intervention on behalf of repressive governments there. An international cam-

paign was mounted against South African apartheid. A small coalition called the Neptune Group helped to broker UN negotiations that led to the 1982 Law of the Sea Treaty. Movement related human rights activists in North and South America parlayed Perez Equeval's 1980 Nobel Peace Prize into leverage for victims of oppression. Throughout the century the Peace Prize Committee had broadened both its understanding of peace and the regions from which winners came; in this it reflected the peace movement itself.

The Cold War collapse in 1989 left peace advocates to redefine their movement. On the centenary of the First Hague Conference, about 4,000 delegates representing NGOs around the world assembled in The Hague to help set a UN agenda for a decade devoted to achieving a culture of peace. They explicitly defined themselves as a transnational peace movement consisting of a global network of NGOs that together reflect a world of growing, interactive social movements.

5. *Scholarly Analysis: History and Sociology*

Scholarly conceptualization of peace movements has tended toward a framework of analysis parallel to the historical phenomenon.

5.1 *Peace Movement History*

In the 1970s historical studies of peace movements flowered into a comprehensive field that expanded for two decades more. In some respects it paralleled growth of resource mobilization theory in the sociology of social movements.

Some historians revisited periods covered earlier and researched them more thoroughly. Others updated the story of peace advocacy. New patterns emerged. Given the massive work of Peter Brock, for instance, religious pacifists could be distinguished from and related to peace activists. Continuities emerged, such the growth of international organization from 1914 to 1945, the process of conceptually linking peace to justice and social change (positive peace), and the links between nonviolent activism against war and for human rights. Drawing on early sociologist Ferdinand Tönnies, 'polity' peace advocates (who stressed institutional arrangements for the sake of order) were distinguished from 'community' ones (who valued popular involvement and the well being of diverse peoples). Charles DeBenedetti incorporated much of the new work in *The Peace Reform in American History* (1980). The title was significant: treating peace as a social reform invited attention to the relationships between organizations, ideologies, and social movements.

Much has been done in the subsequent two decades, both to correct imbalances in the accounts of national movements and to connect them. Several historians rescued the vital roles of women in the movement from

the neglect of male authors, for example (see Alonso 1993). Peace historians formed a transnational network of scholars from Europe, America, Canada, Australia, and Japan, working through the *Arbeitskreis Historische Friedensforschung* (German Working Group on Historical Peace Research) and the Peace History Society. Europeans revised Beales, while an American analyzed the nineteenth century European movement in terms of relationships between patriotism and internationalism and among varying class and political groupings (Cooper 1991). Together they studied the relationship of peace movements and political cultures. US and Russian historians produced a joint history of the concept of peace in western history (Chatfield and Ilukhina 1994).

5.2 The Sociology of Social Movements

While historians were interpreting peace advocacy as a diverse reform movement, sociologists were analyzing social movements with resource mobilization theory: what are the terms on which social movements strengthen and use their resources? Basic works in the field date from the 1970s (see *Social Movements: Resource Mobilization Theory*).

The fully developed method was applied to peace movements in the 1990s, especially to the Freeze campaign of the previous decade but also in a comparative analysis of three US peace coalitions. Most recently, modified resource mobilization analysis has been applied to the dynamics of transnational NGOs and social movements (see Smith et al. 1997). One study demonstrates the inter-relationships of developing nongovernmental and intergovernmental organizations *before* 1945 (Chatfield, Chap. 2 in Smith et al. 1997), and Wittner reifies the transnational social movement model with a longitudinal study in the period *since* then (Wittner 1993, 1997).

Besides filling out the history of specific peace movements, therefore, the future of this field is likely to involve narrative and analysis of more transnational connections among peace and related movements. Future scholarship may well explore specific peace and antiwar movements as dynamic elements in the creation of transnational infrastructures in an increasingly integrated world.

Peace Movements, History of

Peace movements are social and political movements appearing since the early nineteenth century as a result of a collective effort to organize pacifism. They can be long-term phenomena aimed at a lasting peace. Alternatively, they can be stimulated by a concrete situation ready to vanish the moment the movement has reached its objective or pass into a latency period to be reactivated only if need be.

1. Peace Movement and Pacifism

Today both terms are frequently used as synonyms. This is even more justified as continental European peace activists adopted the term 'pacifism' the moment it was coined and widely picked up by the sociopolitical language. It proved to be useful as it suggests

a triple meaning i.e., 'movement,' 'theory,' and 'radicalism.' Anglo-American usage often makes a distinction between 'internationalism' and 'pacifism' with 'internationalism' comprising the moderate demands of peace movements in their entirety whereas 'pacifism' means the idea of the greatest possible radicalism in the practice of peace including absolute refusal to serve in the military. Based on British conditions Ceadel offers an elaborate distinction between 'pacifism' and 'pacifism' (Ceadel 1980).

2. *Origins*

The French Revolution first created conditions that allowed peace movements to arise. On the whole, they remained restricted to the European-North-Atlantic sphere far into the twentieth century. Convictions matured within the pre-Revolutionary bourgeois society that there is no rational argument to justify war. The mass experience of war following the French Revolution of 1789 and Napoleonic rule gave the impulse for the organization of an individual peace mentality. The peace movement draw important program elements from a store of peace prospects dating back to Judaic-Graeco-Roman antiquity and early Christianity which manifested themselves in christology based, eschatological expectations of religious movements that included the vision of a non-violent society and in the religious practice of Christian peace sects (Brock 1991a) as well as in literature, the arts, philosophy and political science. Apart from the singularity of Gandhi in India (Brock 1983, Kozhuvanal, in: Brock and Socknat 1999) no indigenous nuclei for peace movements are to be found outside the European-North Atlantic sphere with the exception of Japan where they began appearing at the end of the nineteenth century particularly in connection with the reception of Christian ideas (Powles, in Brock and Socknat 1999), while other moves to organize pacifism starting around 1900 in Australia, New Zealand, Latin America, and even in Japan had either been dependent on or inspired by the Anglo-American model (see Fried 1972).

3. *The Starting Period*

The time spanning from the end of the Napoleonic era to the beginning of the age of imperialism was a take-off period for peace organizations. They emerged from two sources: on the one hand, religious motivation particularly characteristic of Mennonites and Quakers in North-America and England (Brock 1990, Ceadel 1996), which led to the founding of peace societies in New York and Massachusetts in 1815 and London 1816 and on the other hand a predominantly philanthropic rationalistic motivation leading to the foundation of the first peace societies on the continent in Paris in 1821 and Geneva in 1830. The discourse of

both focused on how to ban war as a means of conflict resolution and to get this idea generally accepted nationally and internationally.

3.1 *Difficult Dialectics*

All attempts to come to grips with this problem caused by the revolution of 1789 proved to be difficult. While the social organization to ban war had been possible, peace movements had to face a new type of war that was another by-product of that secular transition. National societies turned nation-states made a concept of war feasible completely different from every preceding one, i.e., it mobilized the nation as a whole with the total annihilation of the adversary as the final goal. The concept of peace based on rationalism arose from bourgeois society yet the same society due to its increasing economic and political dynamics carried an inherent potential for war the dialectics of which constitute the peace movements' field of activity during the nineteenth century until the World War I.

3.2 *Differences and Correspondence*

The general development assumes a different profile in every individual nation-state (van der Linden 1987). The US peace movement owes its origin to a very specific situation (Brock 1968). In Europe's young nation-states Italy and above all the German Empire (national peace societies founded in 1887 and 1892 respectively) the development occurred with considerable delay and had a nature different from that of the British Empire, a well established nation-state, or France a nation-state having aspirations towards Europe and overseas or a multinational state like Austria-Hungary (Austrian peace society founded in 1891). It is of significance whether a country has a stable parliamentary system including minority and nonconformist groups into the national consensus or if a country is characterized by a weak parliamentary structure and/or authoritarian leadership structure as well as a tendency to marginalize dissenting political views (see Ceadel 1987).

Notwithstanding their different national conditions all peace movements of the nineteenth century have a lot in common with regard to their homogenous appearance, their organization, and their means of communication. They use societies and associations typical of the bourgeois society of the nineteenth century. The growing participation of the radical bourgeois women's movement gains importance (see Bortolotti 1985). Communication was established via national and international congresses and a broad spectrum of literature. The result was a well-organized pacifist International, whose cohesion was strengthened by the foundation of the International Peace Bureau in Bern in 1892, and remained almost intact until World War I.

Peace activists were convinced that their concept of the need for peace could be most effectively promoted by individual powers of persuasion. Cognitive learning was believed to be the most effective method for instilling an understanding of the need for peace. That is why great importance was attached to schooling and national education as 'indirect means of peace.' Peace activists believe peace as well as war to be due to an individual act of will. This conviction led to appeals for peace addressed to the rulers and delivered at international congresses (Brussels 1848, Paris 1849, Frankfurt am Main 1850, London 1851, Manchester 1852, Edinburgh 1853). This continued on a universal level with the First Universal Peace Congress in Paris in 1889. The prerequisite for this was social homogeneity within the urban society as represented by merchants, industrialists, bankers, physicians, civil servants, professors, teachers, as Chickering shows for Germany (Chickering 1975). Protestant backgrounds show significantly greater receptiveness to pacifist recruitment than Catholic ones. In countries with a predominantly Catholic majority like Italy the willingness to embrace pacifism is characteristically present in connection with economic prosperity, liberal and/or republican convictions rooted in the Risorgimento, freemasonry, etc.

Eventually the social question vanished from the agenda of the international peace movement despite the considerable contributions of renowned socialists and anarchists in organizing pacifism from the left as early as during the inaugural congress of the International League of Peace and Liberty in Geneva in 1867. This corresponds to the increasing distance between the labor movement and the peace movements. In Germany, the distance is biggest, whereas it is substantially less in France and Italy and almost non-existent in England. The sooner the labor movement had separated from bourgeois democracy while opening up to Marxist theory the more brusquely it emphasized the distance from the peace movements. For the German peace movement cooperation with social democracy remained a top priority, that long went unrealized. In accordance with their bourgeois nature, peace movements maintained regular contact with liberal parties. Wherever political liberalism became diversified like in Germany the peace movement joined left liberalism because of its manifest inclinations towards internationalism, whereas national liberalism accused the peace movement of lacking national identity, and participated in stigmatizing pacifists (Holl 1988b).

Revolutionary wars did not present an argumentative problem to the early peace movements as long as the goal of these wars was national unity (van der Linden 1987). Behind this position was the expectation that lasting peace would set in with the elimination of reactionary governments at the hands of national movements. For the bourgeois left who were active in the early peace movements war for national unification

was legitimate and the last of all wars to be fought. Having found its destiny within the nation-state, a country was expected to fit into the community of nations and to submit to the international legal system in case of conflict. Pacifist arguments also legitimized national defensive warfare necessary to secure the goal reached in the process. S. E. Cooper has coined the term 'patriotic pacifism' for this position (Cooper 1991). The position on revolutionary warfare looked quite different with regard to social revolutionary goals, all the more when socialism began to dissociate itself from peace movements. Ever since bourgeois pacifism's rejection of war has been influenced by the fear that warfare could result in a social coup.

The British peace movement viewed obstruction of international free trade as yet another legitimate reason for war. In connection with the struggle over the Corn Laws economic interests were combined with pacifist propaganda. The international peace movement joined forces with the free trade movement resulting in an organizational symbiosis (Ceadel 1996) and the development of something along the lines of 'free-trade pacifism.'

As a bourgeois reform movement, the international peace movement joined abolitionism leading pacifism, utilitarianism, Quakerism, free-trade policy, and anti-slavery agitation to come together. Faced during the American Civil War with the conflicting aims of the abolition of slavery and maintenance of national unity on the part of the northern states and the defense of slavery and free trade on the Confederate side, the international peace movement leaned in the end towards the union while Quakers on both sides objected to military service (Brock 1968).

3.3 The Methods Propagated

The methods propagated for achieving and securing peace are twofold. As the prevailing state of affairs in international relations was perceived as 'international anarchy,' peace movements proposed a fundamental reform of these relations and suggested the creation of a legal codex. Concepts were discussed for legal procedures of conflict resolution to be enforced by an international tribunal and a court of arbitration with either facultative or compulsory arbitration. The underlying conviction was the call for 'peace through justice' that stimulated the origins of pacifist international law. The inherent idea was to restrain military influence on foreign affairs.

To the extent that the volatile nature of the national movements and the possibility of their exploitation by the cabinets were recognized as threats to peace, the call was made for fraternization and concepts for a league of nations on the basis of a free federation of European nations, republican constitutions, and the autonomy of communities to thus circumvent the state as a basis for social organization. This was propagated

at the Geneva Congress in 1867. In the end, corresponding attempts to organize based on Proudhonism had no chance. Continental peace movements preferred to propagate the 'United States of Europe' instead.

4. *The Age of Imperialism*

From 1901 onwards the supporters of peace movements called themselves 'pacifists' and their program 'pacifism.' Having the advantage of multilingual usability, the term met the requirements of an international movement. Earlier names such as 'friends of peace' finally vanished. The new term signaled an advanced level of theory and the intention of expanding the social base. The creation of the term reflects the success of both socialism and social Darwinism as social theories, and of imperialism. The spread of social Darwinist thought in Europe and in the USA that led public opinion to be more favorably disposed to imperialism and warfare had a negative effect on pacifist campaigning. Owing to its Eurocentrism and its inclination to cultural imperialism the international peace movement itself was occasionally susceptible to the imperialistic zeitgeist. The growing crisis of the global system incited the international peace movement and eminent pacifist authors to develop new concepts and theories (Grossi 1994).

Since the end of the 1860s new peace movements sprang up emphatically propagating peace negotiations by arbitration. Tsar Nicholas II's peace manifesto (1898) and the First Peace Conference in The Hague (1899) proved to be false confirmation of the movement's demand for disarmament. Despite this seeming success the peace movement's societal position remained marginal in Austria and Germany where it faced male prejudice not least because of the participation of the radical bourgeois women's movement and due to the fact that Bertha von Suttner, in whose novel *Lay Down the Arms!* (1889) a woman's concern about world peace is expressed, took a leading position in the peace movement (Holl 1988b). In his oeuvre *War in the Future in its Technical, Economic and Political Aspects* (1898) Jan Bloch predicted, against all social Darwinist and strategic expectations of the time, the disastrous consequences which were confirmed by World War I. A. H. Fried developed a peace theory he termed 'organizational pacifism' which ruled out world war because the growing network of international relations would prevent it for utilitarian reasons. Fried's theory won support from Norman Angell's book *Europe's Optical Illusion* (1909, extended 1910, *The Great Illusion*) that held future wars to be economically futile because of the interdependence of national economic interests.

The ineffectiveness of the peace movement gave way to further pacifist concepts on the eve of World War I. Their aim was to win prominent leaders in academic circles for international understanding. Their target

in Germany was the 'Verband für internationale Verständigung,' founded in 1911 (Chickering 1975). Furthermore there were efforts promoting bilateral international understanding and supported by the international peace movement: on a Protestant church-based level for instance between England and Germany, and on a parliamentary level between French and German MPs. Independent from such phenomena, communities which lived according to the principle of absolute non-violence continued to exist with particularly those groups following Tolstoy's teachings receiving the greatest public attention (Brock 1991b).

5. *World War I*

World War I created a deep rift within the international peace movement and cut the national peace movements' flexibility to a considerable extent. The experience of war, during which traditional peace societies held on to their patriotic pacifism led to the founding of pacifist organizations with a new style and program expressing the radical pacifists' frustration with the insufficient prewar peace societies. This ended the older pacifism's abstinence from domestic policy as the dependence of foreign policy on domestic conditions was scrutinized. In Germany, the 'Bund Neues Vaterland' demanded politics of domestic reform (Holl 1988b). The British 'Union of Democratic Control' called for a new foreign policy without secret diplomacy. In addition resolute pacifism organized in the Netherlands, 'Nederlandse Anti-Oorlog-Raad,' and in the USA, the 'League to Enforce Peace.'

The new pacifism formed a more solid base for international organizations: The international congress of pacifists in the Hague in 1915 led to the short-lived 'Central Organization for a Durable Peace.' The 1915 Hague congress of women war opponents, which was rooted in the radical bourgeois women's movement, ended with the foundation of the 'International Women's Committee for a Lasting Peace' which led to the 'International Women's League for Peace and Freedom' in Zurich in 1919 (see Schott 1997). Inspired neither by the old or new style peace movements nor by Gandhi and Tolstoy's teachings, refusal of military service surfaced for the first time as a mass phenomenon, particularly in Great Britain, where objectors joined the 'No Conscription Fellowship' during World War I.

6. *The Interwar Years*

During the interwar period, peace movements were marked by the coexistence of radical pacifist positions with the moderate orientation of traditional peace organizations and a widening of their social base into the working classes. While radical pacifism expressed

itself in the mass-movement 'No More War,' organizational pacifism lived on in the call for the 'League of Nations' that found outstanding support in Britain. The new peace organizations in France and England differed from the German peace movement in their judgment of the imminent threat to world peace posed by right-wing dictatorships. In France, the 'Ligue internationale des Combattants de la Paix' emerged as the mouthpiece of integral pacifism in the 1930s. It played down the threat of war emanating from Nazi Germany, attacked French defense policy, and demanded strict neutrality towards current military conflicts, a position that could well have led to collaboration during German occupation (Ingram 1991). This attitude corresponded to the British 'Peace Pledge Union,' which began to loose ground only after the obvious failure of the British appeasement policy (Ceadel 1980). With the beginning of national socialist rule, the German peace movement was forced into exile or exposed to persecution (see Holl 1988a).

7. After World War II

The nuclear attacks on Hiroshima and Nagasaki as well as the postwar strategy of nuclear deterrence developed in the course of the East-West confrontation gave new dimensions to the discussion on war and peace. Originating from the USA and directed against the Vietnam war, a radical peace movement staging a new type of mass protest and with the characteristics of the 'New Social Movements' came into being (see Breyman 1998). In accordance with nuclear pacifism, this peace movement argued that nuclear war of aggression, nuclear preventive warfare, and nuclear defensive warfare were virtually indistinguishable from one another. Additionally, it expressed doubt with regard to the peacekeeping effect of the nuclear deterrence strategy and played up the fear of the nuclear self-destruction of humanity. These arguments motivated the movement's opposition to all weapons of mass destruction. In a large number of Western countries in the 1980s, the new peace movement achieved a mass mobilization against the installation of medium-range NATO missiles in Western Europe that in the end proved futile.

K. Holl

Peace Promotion, Psychology of

Brutal conflicts such as those in Rwanda, Kosova, and East Timor have boosted awareness of the subjective dimensions of war, genocide, and intergroup conflict

and of the need to address hatreds, fears, and emotional wounds of war in building peace. Within a multidisciplinary perspective, this article examines the psychological origins of war and destructive inter-group conflict and psychological approaches to resolving conflict nonviolently and to building peace with social justice.

1. Historical Context

Psychology became prominent partly through helping the US develop government tests for selecting military recruits in World War I. Through World War II, many psychologists contributed to war efforts, although William James, Edward Tolman, and others worked for peace.

Following World War II, social psychologists such as Morton Deutsch, Herbert Kelman, Otto Klineberg, Gardner Murphy, Charles Osgood, Muzafer Sherif, and Ralph White analyzed sources of intergroup tension and methods of nonviolent conflict resolution, with an emphasis chiefly on the Cold War. The nuclear threat animated large numbers of psychologists worldwide, as researchers such as Robert Jay Lifton, John Mack, and Milton Schwebel examined the psychic impact of living under the threat of nuclear annihilation. Throughout the Cold War, psychological research focused mostly on negative peace, that is, on stopping and preventing war (White 1986), rather than on positive peace, which involves social justice, positive inter-group relations, human rights, and sustainable development.

Following the Cold War, psychologists examined a wider array of peace issues such as women and war, militarism, children and armed conflict, environmental destruction, and postconflict healing.

2. Psychological Sources of War and Destructive Intergroup Conflict

Armed conflicts, including the intrasocietal conflicts that are now the dominant form of war, have complex political, historical, and economic roots. Much destructive conflict originates in a divergence of objective interests, competition over scarce resources such as land and water, and worsening life conditions. The 1994 genocide in Rwanda, for example, had antecedents in land scarcity, social class, and the political and economic privileging of Tutsis under the Belgian colonial regime (Prunier 1995). Many conflicts have their origins in struggles over oil, diamonds, land, and other objective resources.

Armed conflict also has subjective sources such as social identity and ideology. Even when no objective divergence of interest exists, people tend to categorize themselves as belonging to different groups and to

show in-group favoritism in judging people, thereby attaining self-esteem and positive self-identity from identification with the in-group (Tajfel 1982). Typically, they judge others relative to the standards set by the in-group, leading to ethnocentric attitudes and behavior, and they derogate members of the out-group. Identity processes alone do not cause violence, but they set the stage for other subjective processes such as hostile ideologies to generate hatred and fighting. Before the Rwandan genocide, President Habyarimana, a Hutu, used mass media to create an ideology of hatred toward Tutsis. Similarly, Hitler used an ideology of racial superiority and global Jewish conspiracy to fuel anti-Semitism and enable the Holocaust (Staub 1989).

Social identity processes play a key role in inter-ethnic conflicts, often referred to as identity conflicts. Ethnic groups are 'imagined communities' (Anderson 1991) that share distinctive language, religion, social institutions, and origin myths. Ethnic identities exercise powerful emotional influence, as children are taught to love their people, their mother tongue, and their way of life. People learn to define themselves by reference to the larger group (e.g., 'I am Russian'), to experience unity with the group, to be patriotic, and to make sacrifices for the group. The sense of unity and solidarity, integrated with a powerful sense of homeland and a sense that the group requires protection, may fuel nationalism and separatist desire for an independent national state.

Conflict escalation often stems from the interplay of objective and subjective factors. As conflict over resources escalates, negative psychological dynamics come into play, and these become self-perpetuating parts of the conflict process (Rubin et al. 1994). Each group tends to create enemy images—demonizing, exaggerated stereotypes of the 'other' that amplify fear and motivate aggressive action (White 1984). These images bias perceptions, leading adversaries to make negative attributions or inferences about motivations regarding the 'other's' behavior. For example, building military forces could be motivated by desire for security, but an adversary who harbors enemy images tends to perceive such actions as having hostile, offensive intent. Negative perceptions and fears on both sides fuel behaviors that the 'other' regards as threatening, contributing to malignant conflict spirals that tend to become self-fulfilling prophecies. By using public media to propagate enemy images, leaders mobilize society for war and genocide.

In a destructive conflict, damage to the parties' relationship becomes part of the conflict, and the emotional and social wounds encourage fighting. Viewing the other side's actions as transgressions, each party sees itself as a victim, constructs collective beliefs or myths about the traumas inflicted on it, and believes that violence is necessary for self-preservation (Volkan 1997). Further, the parties tend to become highly polarized, and intragroup pressures discourage con-

tact with the other side, which is viewed as having incompatible goals. In protracted conflicts, each side may come to view itself as irreparably opposed to the other side, leading to an ethos of antagonism and a tendency of each group to define itself in part via opposition to the other.

Subjective influences are visible also in the biased decision-making of policy elites. Many leaders' aversion to losses encourages excessive risk-taking and departure from rational decision making. In intense conflicts, leaders may experience powerful fears, which motivate misperceptions regarding their adversaries' motives, strength, and willingness to fight. As intercommunal tensions escalate, leaders may experience a cognitive constriction evidenced in reduced complexity of views of the adversary expressed in speeches. Leaders may also use inappropriate historical analogies to guide thinking about current crises. Under pressure of crises, small leadership groups having a strong *esprit de corps* and a charismatic leader may make flawed decisions guided by premature consensus, a sense of invulnerability, failure to weigh moral concerns, internal suppression of dissent, and poor contingency planning (Janis 1982). In a variety of contexts, obedience to authority is a powerful enabler of armed conflict, human rights abuses, and even genocide (Kelman and Hamilton 1989).

3. Nonviolent Conflict Resolution

Conflict can be constructive when it is managed in ways that promote communication, healthy relationships, and a sense of positive interdependence (Deutsch and Coleman 2000). To handle destructive conflict nonviolently, psychologists have developed or refined numerous tools designed to resolve conflict and to transform or repair damaged relationships (Rubin et al. 1994).

Negotiation, the handling of conflict through communication and bargaining by the parties themselves, has important psychological dimensions. If, as often occurs in official diplomacy between hardened adversaries, opponents view negotiation as a win-lose affair, they may dig into entrenched positions and use damaging, coercive tactics such as threats. Psychologically, a more useful alternative is principled negotiation, which reframes negotiation as a win-win affair. In this approach, parties collaborate to solve their problems and seek not to beat the opponent but to enable all parties to meet their underlying needs, thereby contributing to improved communication, empathy, and relationship. Which approaches to negotiation are likely to succeed depends not only on the situation, the kind of issues at stake, and the amount of fear and relational damage, but also on culture. For example, US negotiators favor direct communication and emphasize what is said, while Asian negotiators often communicate indirectly, re-

lying on context and maintaining group harmony by avoiding direct confrontation.

Strong mistrust, fear of appearing weak, and poor communication can make negotiation infeasible. In this situation, a preferred approach is mediation, in which a third party helps the parties to negotiate a settlement. By proposing alternatives that the parties may not be willing to suggest themselves, mediators enable face-saving. They may also use social influence processes such as 'carrots and sticks,' a mixture of promised rewards for conflict reducing steps and promised punishments for intransigent behavior. Skilled mediators manage the conflict process, separating the parties when they are likely to say or do damaging things.

Official diplomacy, however, is limited since hardened adversaries may be unwilling to meet publicly. Also, public agreements can evoke backlashes, and official treaties may not change the polarization, fear, and hostility present in divided societies and communities. Kelman has pioneered the use of interactive problem-solving workshops (Fisher 1997) as a tool of unofficial diplomacy and relational improvement. Regarding the Israeli-Palestinian conflict, a typical workshop brings together three to six Israelis with an equal number of Palestinians for three days of private dialogue facilitated by social scientists. In analytic, problem-solving discussion, the participants examine the main issues at stake in the conflict, explore their concerns and fears, and identify possible steps and solutions that could reduce the political and psychological barriers on both sides. Empathy, problem solving, and group exploration of 'what-if?' questions are encouraged. Afterwards, participants take their new learning about the other side back into their communities, beginning the wider process of community transformation. By building positive relationships and infusing useful ideas into conflict-torn communities, this method provides a useful complement to official negotiation.

Positive contact between members of polarized, isolated groups can also reduce destructive conflict (Pettigrew 1998). Positive contact is likely to occur in a context of equal status that enables individuals to get to know each other personally and when steps have been taken to gain leaders' support and prevent damaging behavior. To reduce perceptions that the positive individuals from the out-group are exceptions, one may use cognitive strategies that enable generalization. One useful strategy is to build superordinate group identities, as occurred in postapartheid South Africa when blacks and whites forged larger identities as 'South Africans' and championed the national rugby team.

The most powerful form of cross-group contact involves cooperation toward the accomplishment of shared goals that neither group could achieve on its own. Global problems such as nuclear proliferation, environmental destruction, and the HIV/AIDS pan-

demic provide many possibilities for cooperation on shared goals that mitigates and prevents destructive conflict.

4. Building Peace with Social Justice

Beyond war prevention and nonviolent conflict resolution, peace requires social justice, social equity, and sustainable patterns of living. Psychology has analyzed how beliefs, attitudes, and practices support social injustice and '-isms' such as sexism.

In systems of severe oppression and genocide, there is a pattern of moral exclusion in which out-groups are dehumanized and removed from the moral realm, providing a rationalization for killing them. Similarly, sexism is supported by socialization norms and practices that privilege boys, encourage girls to conform to stereotypic roles, and encourage acceptance of existing patterns of patriarchy. Environmental damage through, for example, the production of mass amounts of toxic waste, often leads to environmental racism via 'not in my back yard' attitudes that encourage storage or dumping of toxic materials near impoverished neighborhoods inhabited by minority groups that lack political power. Efforts toward poverty alleviation may be thwarted by tendencies to blame the victim, enshrined in societal beliefs that people are poor because they are lazy or deserve it.

In promoting social justice, useful psychological tools include steps to increase the sense of positive interdependence between groups, media campaigns that heighten salience of justice issues and indicate specific behaviors that can help address the problem, positive modeling of tolerance and restraint by authority figures, and methods of attitude change. In addition, commitment can often be built through the 'foot in the door' method in which agreement to a small request increases the likelihood of subsequent willingness to engage in more effortful action. To change behavior on a wider level, one may use community-based social marketing methods that strategically assess points of leverage for social change, pilot selected interventions for changing attitudes and behavior, and replicate the process on a larger scale (McKenzie-Mohr 2000).

Education for peace is essential in building social justice and peace, as most people are socialized into systems of violence (Raviv et al. 1999). In schools, psychologically informed programs have developed skills of nonviolent conflict resolution, encouraged peer mediation of conflicts, enabled cooperative learning that also reduces excessive competition, and built curricula that undermine hatred and stereotypes. Beyond schools, education for peace has included activities to enable constructive handling of family conflict, cross-conflict dialogues in divided communities, and use of mass media to show positive handling

of conflict, to counteract black-white thinking, and to reduce the excessive emphasis on violence evident in television and the war-toy industry.

5. Future Directions

Since wounds of past violence create emotional vulnerability and enable cycles of violence, building peace requires the healing of emotional wounds and reconciliation. Programs of humanitarian assistance and development increasingly include psychosocial activities aimed at healing the wounds of war through normalizing activities, expressive arts, reintegration of former child soldiers, and use of local cultural networks and resources. A key task for the future is to find the most effective, culturally appropriate ways of rebuilding torn societies. There is great need of research on reconciliation, the repair of damaged relationships, and its connection with processes such as truth-telling, forgiveness, and establishment of justice. As psychology addresses these issues, it will examine a wider array of cultures and develop theories that connect microlevel change in individuals and small groups with macrolevel changes in societal and international structures.

Peacemaking in History

1. Definitions

1.1 Peace and War

War is declared, begun or unleashed, or it breaks out; peace is concluded, settled, agreed or imposed. Ordinary language thus shows an important asymmetry: war is either the outcome of forces neither side can fully control, or the result of one-sided action, while peace has to be established in an effort involving both sides, unless it is simply the result of the dying out of fighting or of the annihilation of one side. For the purpose of this article, *peace* is defined negatively as absence of war and other forms of widespread collective fighting. This static definition does not do justice to the concept of peace as a movement, a process of improvement with stages in between just a momentary absence of war and ideal, eternal peace and harmony. But this positive, dynamic view of peace concerns a different subject; this article deals only with the crucial transition from a state of war to a state of peace. *War* is defined as a state of collective armed violence between politically organized, at least *de facto* and usually *de jure* independent communities, during which special law is valid. The main characteristic of this law is the relaxation of the rules which prohibit killing. War does not presuppose continuous fighting. But if fighting ceases altogether, one can speak of a *de facto* peace. Fighting without application of different law is not war, but anarchy or rebellion. If, later on, the law of war is recognized by both sides, the rebellion or the anarchy has developed into *internal* or *civil war*. Civil war occurs between parties originally forming one political community, while war between independent communities is *external* or *international war*.

With respect to peacemaking, one fundamental aspect of war has to be mentioned: war has inevitably the character of an ordeal, of a 'judgement of God,' as power and not justice decides its outcome (Kant 1968).

1.2 Peacemaking and Pacification

Peacemaking is defined as transition from a state of war to a state of peace by a deliberate action of the parties involved. Departing from a differentiation between three types of peace introduced by Raymond Aron: equilibrium—hegemony—empire (Aron 1962), peacemaking is here placed between two extremes which mark ideal types. *Peacemaking proper* is characterized by coordination, and hence by full legal (although not necessarily material) equality and independence of the parties. If there is a new conflict between them, it will be international war. *Pacification* is characterized by subordination. It implies the legal extinction of one party as an independent entity by its incorporation into the other. Usually, it is connected with an ex post denial of the vanquished's right to conduct war by the victor. If there is a new conflict, it will start as a rebellion and may develop into a civil war. Each concrete case of war termination can be situated between these two extremes. For pacification, an overwhelming victory of one side is a necessary condition, whereas peacemaking proper tends rather to be linked with a stalemate. But the relative strength of the parties is not the only factor deciding the outcome. There are periods in history during which pacification prevails.

2. Peacemaking Before the Twentieth Century

The roots of peacemaking lie beyond the grasp of written sources. Anthropological research as well as written evidence of transactions between literate and nonliterate political communities suggest that wherever there is fighting between politically organized groups, there are also mechanisms to end fighting on more than just a *de facto* basis, which presupposes some reciprocally recognized arrangements, and thus some reliability and stability. Special oral procedures to memorize the contents of the transactions are developed (cf., e.g., the highly elaborate methods of the North American Indians in their dealings with the Europeans in the eighteenth century, which the Europeans had to adopt as long as they could not simply dictate the terms (Franklin 1938)). While the material stipulations can vary considerably according to the way of living of the peoples involved, the most important and the most difficult arrangements concern guarantees for the keeping and carrying out of the stipulations. Whatever the intention of those who conclude the peace, its oral form tends to limit its scope in time and in space. Frequent renewal, especially after the death of the head of one of the contracting parties, is the most important method to maintain the force of the agreements. Wherever writing develops, peace treaties are among the first instruments for which it is used, and they are frequently written on the most durable materials, like

stone or metal. The oldest treaties preserved date from the third millennium BC in the Ancient Near East. They are to be seen in the context of the pacification of vassals, while the first known treaty between great powers is from the thirteenth century BC, between the Hittite and the Egyptian empires. The problem of guarantees is dealt with by oaths and by the invocation of the intervention of deities, while in other cases hostages are given, either unilaterally or reciprocally, or dynastic matrimonial unions link the destinies of the two parties.

In the course of time, the main topics of peacemaking, besides peace itself and its guarantees, turned out to be territorial, financial and economic. Sometimes they were supplemented by clauses dealing with the destiny of certain populations. Peacemaking proper was almost invariably connected with an amnesty for those who had supported the enemy during the war, based on a more general promise of reciprocally forgiving and forgetting what had happened during the war. The contracting parties were to behave as if peace had never been interrupted, thus marking a sharp contrast between war and peace. There was also a strong tendency in all parts of the world to stress the perpetual character of the peace concluded, not so much as an expression of a realistic expectation but rather as a reminder of a general characteristic of peace (Fisch 1979).

Whether peacemaking proper or pacification prevailed in a certain period and in a certain area, depended to a great extent on the general nature of the relationships between political entities. Well-documented genuinely pluralistic systems of a balance of power (which tend to foster peacemaking proper) are rare. The cases which probably came nearest to it were relationships between the Greek city states in the fifth and fourth centuries BC and between the Hellenistic states before the Roman conquest. Even here, there were tendencies for hegemonies to develop as with Athens or Sparta in Greece. Later the Greek system was absorbed by an empire, first Macedonia and then Rome. It is however to be supposed that in areas and periods with many smaller political entities, of which we have few written sources, peacemaking proper was also the rule. In international systems built around powerful empires, on the other hand, there was a strong tendency to pacification, certainly in the formal, although less in the material sense. Great empires, among them the Roman, the Chinese, the Islamic Khalifate, and the Ottoman and the Mogul Empires, frequently showed a reluctance towards peacemaking proper, claiming some kind of overlordship over their neighbors and rivals. They tended not to conclude formally reciprocal treaties with them but to impose unilateral edicts on them, or else they limited the duration of treaties. The Islamic doctrine, for example, allowed no peace but only armistices of up to 10 years with non-Muslims. Peace was not agreed, but granted. However, reality often belied

these pretensions; *de facto* the solution was frequently one between equals, and sometimes the empire was even in the weaker position.

In European history there is a somewhat different interplay between peacemaking proper and pacification. In the Middle Ages there were two trends towards pacification. On the one hand, the Emperor had a claim to supremacy over all the rulers of Christendom. In practice, this claim had hardly any importance; peacemaking among the great monarchs was legally and formally reciprocal. Thus, the basic structure of peacemaking in Europe after major wars was peacemaking proper long before 1648. Much more important with respect to pacification were, on the other hand, feudal relations between lords and vassals on various levels. Vassals tried to acquire full independence, which included the right to be a party in war and thus to become a subject of peacemaking, while lords tried to gain full control over their vassals, which led to attempts at pacification. The result of the century-old struggle was a balance of power-system with fully sovereign entities which, among themselves, practiced only peacemaking proper. In some countries, the ruler (usually a king) had been able to subjugate his vassals by methods of pacification, while in others, especially in the Empire, the vassals had gained full or almost full sovereignty.

Modern European history from the sixteenth century, and even more from the seventeenth century onwards, is thus characterized by a system of legally strictly equal relations. In its framework, particular methods of peacemaking were further developed. During the war, various kinds of peace feelers would be extended. Frequently, mediators played an important part, either as honest brokers or as great powers which tried to influence the settlement according to their own interests (on mediation in general, see Touval and Zartman 1985). The process of peacemaking proper tended to be broken up into three stages: armistice, with cessation of hostilities and, frequently, important material settlements—preliminary treaty, containing the core of the settlement—definitive treaty. This was, however, never a necessary pattern. Preliminary peace treaties played a really significant part only in the 19th century. Frequently, the most important decisions were taken even before hostilities ended (Pillar 1983). One of the most salient features were the peace congresses after general European wars, especially those in 1648, 1713, 1814–15, and 1919. The first of them, in Münster and Osnabrück, which led to the Peace of Westphalia, was an important stage in the development of a European system of legally equal, sovereign states. But it was not, as is frequently claimed, the point of departure for this system, which had much older roots. Such congresses developed general, often multilateral settlements which were likely to be more stable than mere bilateral peace treaties. Their success was remarkable, especially after the Congress of Vienna in 1814/15,

which constituted a kind of joint hegemony, combined with a joint responsibility for the peace, of the great powers. But after all, general peace settlements had as their corollary general wars.

This was, however, but one side of modern European peacemaking. The European states conquered, from the sixteenth to the twentieth century, vast parts of the world. In many areas of Asia and Africa, peacemaking proper between Europeans and non-Europeans was the rule up to the nineteenth century. Especially in America, there were widespread attempts at pacification. They were frequently successful: the extra-European rulers were brought into a legally subordinate position. This happened even in areas where, at first, there had been peacemaking proper, especially in India and Indonesia. The difference was felt by the contemporaries. In Spain, for example, *pacificación* officially replaced *conquista* in 1573, showing the origin of the concept in conquest and not in peace. Yet pacification was often merely a fiction, because the colonial power was too weak to impose its will. Nevertheless, in the long run, pacification tended to become the rule in most colonial dealings.

Thus, at the beginning of the twentieth century, the European experience was one of peacemaking proper in Europe and of frequent pacification outside Europe. For both purposes elaborate and successful techniques had been developed. But this also meant that war was a well-known feature of international life. One tried to avoid it as far as possible; nevertheless it belonged to the accepted experience. This acceptance was to be challenged in the twentieth century.

3. Peacemaking in the Twentieth Century

The First World War began as a traditional European war. The fierceness of its fighting and the destructiveness of modern weapons increased the number of combat casualties beyond that of all previous wars. This led to increased demands for the outlawry of war, that war should no longer be considered as a legitimate means of politics but as a crime, and propaganda on both sides tried to depict the enemy as a criminal.

The Second World War further strengthened the view that war was a crime, while the postwar period brought, with thermonuclear weapons, for the first time in history the possibility of a war destroying mankind altogether, so that peacemaking would be neither necessary nor possible. This did not mean, however, that smaller wars had become impossible.

These developments had consequences for peacemaking. The Covenant of the League of Nations, which was part of the peace treaties after the First World War, prohibited war at least to a certain extent (articles 10; 12–15). The Briand–Kellogg Pact of 1928 brought the renunciation of war as a means of national politics, while the UN Charter of 1945 prohibited the

use of force—and thus war—altogether, with the exception of legitimate self-defense (articles 2, 4; 51), which was no real exception, as self-defense is the answer to an aggression which in turn is prohibited. Combined with the outlawry was the attempt to prevent war by a system of collective security which would replace war by police-actions of the totality of the member-states against a peacebreaker. Ideally war would have been abolished altogether by this system. But it was weak, because neither the League nor the UN had enough coercive means of its own and even less the power monopoly which would have been needed in order to reduce warfare to an efficient system of policing.

At least in theory, the outlawry of war excluded the possibility of peacemaking proper. If one side was guilty of a criminal act there could be no peace on the basis of legal equality but only punishment. Yet, as there was no efficient system of policing, war still maintained its character of a judgment of God, and there was no guarantee that the guilty party could be punished. Peacemaking reflected these facts. It tended to join elements of both peacemaking proper and pacification, the mixture being dependent on the outcome of the war. After the First World War this meant a combination of the intra-European and of the colonial tradition. There was a peace congress, but with the losers excluded, and there were peace treaties, but with the vanquished formally admitting their responsibility for the war, thus being placed into a legally inferior position. This tendency was increased after the Second World War, when the vanquished were not only deemed, and had to confess themselves, guilty of the crime of aggression, but their leaders were brought to trial for their crimes and their states were occupied and administered by the victors. Especially after the World Wars there was a tendency by the victors to devise definitive solutions at a very early stage of the negotiations if they did not simply impose them by instruments of surrender or armistices.

Peacemaking in the twentieth century outside the context of the World Wars followed this pattern to a great extent. Theoretically, or rather dogmatically speaking, there was no longer any room left for peacemaking proper. But wars could still lead to a stalemate and render traditional peacemaking necessary, although there might be no traditional final peace treaty. A particularly elaborate example was the termination of the Vietnam War 1968–73/5. Thus, peacemaking proper has maintained a certain importance in the context of the termination of wars, and it is likely to keep it as long as there is no efficient global system of policing, although the relevant activities of the UN have increased, especially after 1989, in the shape of peacekeeping and peace enforcement. Peacekeeping often takes the place of a provisional arrangement instead of formal, definitive peacemaking, while peace-enforcement has the character of an imposed mediation. The proliferation of

civil wars in recent years has even increased the importance of some traditional techniques of peacemaking, as the coexistence of former civil-war parties makes reconciliation more important than it is between independent, separate states.

4. *The Conditions of Peace: Research into Peacemaking*

It is an almost stereotyped complaint in the literature on peacemaking that, compared with research into the causes of war, very little research into the causes of peace has been carried out. This is, however, not so much the consequence of a predilection for war or even a warlike disposition of the researchers, but rather of a basic difference in the public appreciation of war and peace. In a prescientific view, war has causes, while peace has not, in the sense that peace is considered as the ordinary and war as the exceptional state of things, even though in reality periods of peace may be shorter than periods of war. The wish for peace usually does not have to be justified in the same way as the wish for war. A state of war sooner or later ends in some kind of peace, while a state of peace does not necessarily lead to war.

The scant research on peacemaking seems to be one of the consequences of these facts. Moreover it is difficult to conceive of causes of peace in a scientific sense. Peace has been successfully concluded in extremely diverse political situations, and there are no methods to calculate the probability of peace in a specific constellation.

Traditionally, peacemaking is a central object of historiography in general and of diplomatic and military history in particular. The focus is usually on individual wars and their termination. Favorite objects of research have been the plans for permanent or perpetual peace through the ages (as an introduction cf., e.g., Hinsley 1963) and the main general peace congresses from 1648 to 1919 (cf. summaries of Holsti 1991 and Osiander 1994), while a comprehensive account of the termination of World War II has yet to be written. Such research helps to understand particular cases of peacemaking, but it usually is little concerned with general causes. More systematic, comparative research has occasionally been conducted during great wars, with a view to facilitate peacemaking. This led neither to more sophisticated systematic accounts nor to the search of causes of peace, but rather to surveys of the range of material regulations of earlier peace settlements (cf., e.g., Phillimore 1917 and Phillipson 1916). The only and very important exception is Quincy Wright's influential *A Study of War* (1965), first published during the Second World War, which, however, was the result of a project initiated long before the war. Wright does not only deal with causes of war but also with causes of peace.

After 1945 there was an apparently paradoxical development. In the social sciences, the threat of an all-destructive thermonuclear war gave, especially from the 1960s, a boost to peace studies and peace research, with the *Journal of Conflict Resolution* (since 1957) and the *Journal of Peace Research* (since 1964) as leading organs. But as peacemaking was no feasible possibility in the context of a thermonuclear war, the central object was the prevention of war and the preservation and improvement of peace. Nevertheless, as experience showed the possibility and the reality of many smaller wars under the umbrella of the thermonuclear stalemate, war termination and peacemaking became the object of at least some studies in the social sciences, especially under the influence of the extremely difficult termination of the Vietnam War (cf., e.g., Fox 1970). In addition, there was the older tradition of more historically oriented research. Hentig (1952) dealt with the general modalities of peacemaking, while Fisch (1979) investigated the concepts of war and peace as they were developed in the peace treaties themselves, including the distinction between peacemaking proper and pacification. The most important basis for research in the social sciences became Wright (1965). After him, Raymond Aron's great survey of peace and war (1962) located peacemaking in the context of international studies and of the Cold War. Since the late 1960s there have been a number of studies dealing systematically with possible causes of peace, on the basis of the comparison of a greater or smaller number of war terminations, e.g., Randle (1973), Pillar (1983) and Holsti (1991) or, more formalized, Carroll (1969). On recent research see Massoud (1996). There exists, however, no theory of war termination or peacemaking, and it is unlikely that it can be developed, considering the extremely varied factors which may combine to bring about peace. The same holds for research into the conditions of maintaining a peace once concluded. Research in international law has particularly dealt with the question of the outlawry of war in the twentieth century, but less with its consequences for peacemaking. There is a challenge for new research in the growing importance of international peacekeeping, peace-enforcement and peacebuilding during recent years. For an introduction, see Otunnu and Doyle (1998). But the main problem remains the contradiction between the outlawry of war and situations of stalemate which will go on requiring traditional peacemaking as long as there is no world-wide monopoly of power. In this context, it will be important to compare the present methods of peacemaking and peace-enforcement with the traditional forms of peacemaking and pacification.

J. Fisch

Pearson, Karl (1857–1936)

Most of Karl Pearson's scientific work concerned human beings—he studied inheritance, physical anthropology, and disease—but his significance for the social and behavioral sciences is as a founder of modern statistics. Through the nineteenth century there had been a sense that the astronomers' methods for treating observations—the theory of errors—could be applied more generally. However, the modern conception of the scope and organization of statistics dates from the turn of the twentieth century when Pearson developed methods of wide applicability and put together the components of a discipline—the university department, courses, laboratories, journals, tables. His contemporaries may have done some of these things better but none had so much total effect.

1. Career

Karl Pearson was proud that his ancestors were of 'yeoman stock' though his father was a barrister. At Cambridge Karl read mathematics. Third place in the examinations brought him a college fellowship and the financial freedom to pursue his very wide interests. Pearson qualified as a barrister and studied social, philosophical, and historical issues. He developed his own view of man's place in a post-Christian world, expressing this in a novel and a play as well as through essays; some of those were published in the *Ethic of Freethought* (1888).

In 1884 the essayist and freelance lecturer became professor of Applied Mathematics and Mechanics at University College London. Besides carrying out the usual duties, Pearson took on two books left unfinished when their authors died. W. K. Clifford's *Common Sense of the Exact Sciences* explained the nature of mathematics and it would link Pearson's early general essays to the *Grammar of Science* (1892). The *Grammar of Science* presented the scientific method as 'the orderly classification of facts followed by the recognition of their relationship and recurring sequences.' In later editions the positivist ideas about space and force were joined by an exposition of statistical ideas. The other book, Isaac Todhunter's *History of the Theory of Elasticity*, was the history of Pearson's own specialism. Pearson actually wrote much more of this huge work than Todhunter himself. Pearson's later historical researches—a biography of Galton and lectures on the history of statistics—combined Todhunter's thoroughness with Pearson's own very different awareness of broad intellectual currents.

Pearson moved from elasticity and philosophy to biometry and statistics under the influence of W. F. R. Weldon, appointed to the college in 1890 as professor

of Zoology. Weldon was applying Galton's statistical methods to species formation and Pearson helped him extend the methods. However, Pearson was not just a mathematical consultant, he became a contributor to the biological literature in his own right. The partnership with Weldon was central to Pearson's development and he made his most important contributions to statistical thinking in these early years with Weldon. Pearson wrote over 300 pieces after 1900 but they were on lines he had already established. Of course these works demonstrated what statistical methods could achieve and were part of making statistics a recognized discipline.

In 1901 Pearson, Weldon and Galton founded *Biometrika*, a 'Journal for the Statistical Study of Biological Problems' which also published tables and statistical theory. From 1903 a grant from the Worshipful Company of Drapers funded the Biometric Laboratory. The laboratory drew visitors from all over the world and from many disciplines. Pearson wrote no textbook or treatise but the visitors passed on what they had learnt when they returned home. In 1907 Pearson took over a research unit founded by Galton and reconstituted it as the Eugenics Laboratory. This laboratory researched human pedigrees but it also produced controversial reports on the role of inherited and environmental factors in tuberculosis, alcoholism, and insanity—great topics of the day. In 1911 a bequest from Galton enabled Pearson finally to give up responsibility for applied mathematics and become Professor of Eugenics and head of the Department of Applied Statistics. During World War One, normal activities virtually ceased but afterwards expansion was resumed. However, Pearson was no longer producing important new ideas and Ronald Fisher was supplanting him as the leading figure in statistics. Pearson retired in 1933 but he continued to write and, with his son Egon. S. Pearson, to edit *Biometrika*.

Pearson made strong friendships, notably with Weldon and Galton. He also thrived on controversy. Some of the encounters produced lasting bitterness, those with William Bateson and Ronald Fisher being particularly unforgiving. Following the 'rediscovery' of Mendel's work in 1900, Bateson questioned the point of investigating phenomenological regularities such as Galton's law of ancestral heredity. The biometricians replied that such regularities were established and that any theory must account for them. After Weldon's death in 1906, the biometricians were often miscast as mathematicians who knew no biology. The quarrel about the value of biometric research faded with Bateson's death and Pearson's withdrawal from research into inheritance. Fisher, like Bateson, was a Mendelian but there was no quarrel about the value of statistics. Fisher criticized the execution of Pearson's statistical work but he also considered himself a victim of Pearson's abuse of his commanding position in the subject.

2. Contributions to Statistics

Pearson was a tireless worker for whom empirical research and theoretical research went hand in hand. His empirical work was always serious. He wanted to make a contribution to knowledge in the field to which he was applying his methods not just to show that they 'worked,' but so he would set out to master the field. However, his contribution to statistical methodology overshadowed his contribution to any substantive field. His statistical contributions can be divided into ways of arranging numerical facts—univariate and multivariate—and methods of inference—estimation and testing.

3. Univariate Statistics: The Pearson Curves

Pearson's first major paper (1894) was on extracting normal components from 'heterogeneous material.' However, Pearson considered 'skew variation in homogeneous material' a more serious problem for he held that the normal distribution underlying the theory of errors was seldom appropriate. Pearson (1895) presented a system of frequency curves; these would be of use in 'many physical, economic and biological investigations.' Systems were also developed by Edgeworth, Charlier, Kapteyn, and others, but Pearson's was the most widely used. Other systems have been devised, inspired by his, but none has been as central to the statistical thought of its time.

From probabilistic considerations—which now seem contrived—Pearson obtained a basic differential equation governing the probability density function, or frequency curve, $y = y(x)$:

$$\frac{dy}{dx} = \frac{y(x+a)}{b_0 + b_1 x + b_2 x^2}$$

The constants determine the form of the curve. Pearson developed methods for choosing an appropriate curve and for estimating the constants. His laboratory produced tables to ease the burden of calculation.

While Pearson used these curves as data distributions, he assumed that the estimators of the constants would be approximately normal, certainly in large samples. In the work of 'Student' (W. S. Gosset) and then Fisher the data distributions are normal but the exact distributions of the sample statistics are usually not, though *they* may follow the Pearson curves. 'Student' did his distribution work in Pearson's laboratory but for many years Pearson thought that such 'small sample' work was off the main track and useful only to 'naughty brewers.'

In the Pearson system the normal distribution is just one type. In Fisher's analysis of variance which appeared in the 1920s it is the *only* type. People

schooled in the Pearson system did the earliest robustness studies and one of the continuing roles of the system has been in this area. While Pearson's skepticism towards normality pervades much modern work, the modern approach to inference is so different from his that he is not a direct inspiration.

4. *Multivariate Statistics: Correlation and Contingency*

In 1888 Galton introduced correlation and soon Edgeworth was developing the theory and Weldon was applying the method in his research on crustaceans. Pearson, however, produced the definitive formulation of normal correlation and had the vision that correlation would transform medical, psychological, and sociological research.

Pearson (1896) set out to frame hypotheses about inheritance in terms of the multivariate normal distribution but these were of less enduring interest than his account of correlation and multiple regression. The familiar partial and multiple correlation and regression coefficients appear at this time either in Pearson's work or that his assistant, G. Udny Yule. Soon Pearson and those around him were applying correlation in meteorology, sociology and demography as well as in biometry.

The 1896 ideas formed the basis of a definitive theory, especially when completed by the exact distribution theory of 'Student' and Fisher. But Pearson soon moved on to qualitative, non-normal, and time series data, though not with the same success. Pearson's scheme for contingency, the qualitative analogue of correlation, has latent continuous variables—surprisingly jointly normal ones. Yule, no longer working with him, rejected the scheme. The controversy that ensued had no clear resolution. Pearson toiled unsuccessfully to create a theory of skew surfaces, uniting correlation and skew curves. Time series correlation analysis was another disputed field. Pearson thought of the true correlation between series as obscured by time trends superimposed upon them. The scheme was widely used but in the 1920s Yule criticized it effectively, yet putting nothing in its place.

From the beginning Pearson encountered problems with correlation which have lived in the underworld of statistics occasionally surfacing in fields such as path analysis and structural modeling. Pearson formalized Galton's notion of correlation as measuring the extent to which variables are governed by 'common causes.' He was soon aware of cases of 'spurious correlation' where the natural interpretation is not sustainable. He and Yule—who developed the other standard interpretation of a direct causal relationship between the correlated variables—found numerous pathological cases. They devised treatments but developed no systematic way of thinking about the problem.

Pearson—following Galton—established multivariate analysis. Yet by a curious twist the multivariate data for which Pearson struggled to create a theory of frequency surfaces is often treated by Fisher's 'regression analysis' which was a development from Gauss's univariate theory of errors rather than Pearson's correlation theory.

5. *Estimation: The Method of Moments and Inverse Probability*

Pearson usually found the constants of frequency curves by the method of moments. He introduced this in his first major paper (1894) for he could find no other method for estimating a mixture of normals. Pearson went on to apply the method quite generally. It seemed particularly appropriate for the Pearson curves where the constants determine the first four moments. However, the method was put on the defensive after Fisher criticized it for not being 'efficient'—even when applied to the Pearson curves.

Probable errors (scaled standard errors corresponding to the 50 percent point) for method of moments estimators were derived by Pearson and Filon (1898) using a modification of an argument in the 1896 correlation paper. Pearson had obtained the product-moment estimate from the posterior distribution (based on a uniform prior) and its probable error from a large sample normal approximation to the posterior. In 1898 he assumed that the same technique would always yield probable errors for the method of moments. He seems to have dropped the technique when he realized that the formulae could be wrong but it was reshaped by Fisher into the large sample theory of maximum likelihood.

In 1896/8 Pearson used Bayesian techniques in a formalistic way but he could be a thoughtful Bayesian. Over a period of 30 years he wrote about the 'law of succession,' the standard Bayesian treatment of predicting the number of successes in future Bernoulli trials given the record of past outcomes—the fundamental problem of practical statistics' he called it. Pearson held that a prior must be based on experience; a uniform prior *cannot* just be assumed. Pearson pressed these views in estimation only once when he criticized Fisher's maximum likelihood as a Bayesian method based on an unsuitable prior—essentially Pearson's own method of 1896/8. Fisher was offended by this misinterpretation of his Bayes-free analysis.

There was plenty of improvisation in Pearson's estimation work; it was eclectic, even inconsistent. He was not the consistent Bayesian that Jeffreys would have liked. Pearson used sampling theory probable errors but he did not follow up the results on the properties of estimators in the old theory of errors. Pearson was not unusual in his generation; the theory of errors he found to hand-mixed frequentist and Bayesian arguments. Some of his contemporaries were

more acute but foundational clarity and integrity only became real values towards the end of his career when Fisher, Jeffreys, and Neyman set about eliminating the *wrong* kind of argument.

6. Testing: Chi-squared

Pearson's earliest concerns were with estimation—curve fitting and correlation—though there testing could be done, using the estimates and their probable errors and making the assumption of large sample normality. However, his chi-squared paper of 1900 introduced a new technique and gave testing a much bigger role.

The chi-squared test made curve fitting less subjective. One could now say: 'In 56 cases out of a hundred such trials we should on a random selection get more improbable results than we have done. Thus we may consider the fit remarkably good.' The tail area principle was adopted without any examination. Naturally Pearson enjoyed showing that the fit of the normal distribution to errors in astronomical measurements was *not* good.

Pearson brought chi-squared into his treatment of contingency and by 1916 he had established the main applications of the chi-squared distribution—a test for goodness of fit of distributions, a test for independence in contingency tables, a test for homogeneity of samples, a goodness of fit test for regression equations.

Pearson's distribution theory involved the exact distribution of the exponent in the multinormal density, this density appearing as a large sample approximation to the multinomial. Pearson slipped in the mathematics and used the same approximation whether the constants of the frequency curves are given *a priori* or estimated from the data. Fisher realized the importance of the difference and reconstructed the theory, finding that the chi-squared approximation was valid but the number of degrees of freedom had to be altered.

Fisher continued Pearson's chi-squared work and gave significance testing an even bigger role in applied statistics. Pearson's methods were more or less vindicated by the later work of Fisher and then of Neyman and E. S. Pearson but, as in estimation, his reasons did not pass critical examination.

7. Summary

Of the many statistical techniques Pearson devised, only a few remain in use today and though his ideas sometimes find re-expression in more sophisticated form, such as the correlation curve or the generalized method of moments, there is little to suggest that Pearson continues to directly inspire work in statistics.

Pearson broke with the theory of errors but in the next generation through the analysis of variance and regression the theory was restored to stand beside, even to overshadow, Pearsonian statistics. From a modern perspective Pearson's theory seems desperately superficial. Yet the problems he posed have retained their importance and the ground he claimed for the discipline of statistics has not been given up. Pearson was an extraordinarily prolific author and there is also a considerable secondary literature. There is a brief guide to this literature on the website <http://www.soton.ac.uk/~jcol>

Peasants and Rural Societies in History (Agricultural History)

The concept 'rural societies' is based on the fundamental division in our society between rural and urban, but usually refers to societies dominated by rural areas. It thus has a historical dimension, and is connected with the concept of peasant societies.

1. Terminology

An intense discussion about the concept of peasant studies began in the 1950s. A large body of literature was published in the decades that followed. The discussion centered on the Anglo Saxon world since, unlike English, most other languages do not contain the same clear distinction between peasant and farmer. In German, for example, *Bauer* can mean both peasant and farmer (Rösener 1993). The need of a distinguishing term in English is also connected with the fact that peasant in English (like *paysans* in French) has a derogatory meaning which the German word *Bauer* (or the Scandinavian *bonde*) does not have.

Several contributions in the discussion about peasants and farmers were made from the 1950s until the beginning of the 1970s (important monographs: Redfield 1956, Wolf 1966, and readers: Potter et al. 1967, Shanin 1971). In recent decades, the concept of peasant has been questioned even in the Anglo Saxon world. For example, Tom Scott writes in an overview that the category of peasant 'is so broad as to become not so much an archetype as a stereotype' (Scott 1998, p. 1). However, the discussion which began during the post-war period, still forms a platform for the research on peasant and rural societies. Peasant society was defined on two levels; partly chronologically in relation to earlier and later types of social systems, and partly socially where the peasant society was defined in relation to the overall social structure of which it was a part.

In the case of the last-mentioned level of definition, the peasant society was seen as a part-society with a part-culture, i.e., a part of the large social structure. This formed the basis of the chronological separation of peasants from what was called the 'tribal society' (or even, but not any longer, the 'primitive society').

Such a society was by definition an earlier system, not being a part of a larger social unit. The emergence of the town was identified as a decisive change and resulted in peasants either choosing or being forced to send some of their produce to the town. The establishment of the State and the state authorities has also been identified as a distinguishing factor. With the advent of the State, the peasant society became clearly subordinate to, but also alienated from, a larger social system as such. To some extent, both these criteria can be said to represent the same change. The peasant society has also been described as a part of an overall socioeconomic feudal system, but every peasant society can hardly be seen as part of a feudal system (see *Feudalism*).

At the beginning of the 1970s, Teodor Shanin (in his *Introduction* to Shanin 1971) summarized the discussion and pointed at some of the characteristics that distinguished a typical peasant society: the family farm as the basic unit of multidimensional social organization; land husbandry as the main means of livelihood directly providing for the major part of the consumption needs; specific traditional culture related to the way of life of small communities; and the underdog position, specified as the domination of peasantry by outsiders. Shanin adds that, like every social entity, the peasantry must be seen as undergoing change as a part of a social process, which influences the definition of the concept peasant.

The chronological border, which separates peasants from the modern farmer has also been discussed. The modern farmer not only produces for a market, but all his actions are profit driven. He acts in the same way as other businessmen. The business itself has become increasingly industrial in nature. Different aspects were emphasised in the discussion. Wolf points to the relationship to the market as being decisive. Redfield emphasizes peasant tradition. The Marxists, who later entered the discussion, wrote that when the peasants acted as a group with class consciousness, they became a class in themselves. The Russian peasant researcher Chayanov, had been purged in 1930 by Stalin but his writings from the 1920s, which got a renaissance long after his death, emphasized the preservation of the family as being of central importance to the peasant (Chayanov 1966).

The discussion illustrates the complexity of the concept, and much of the discussion focused on the problem of definition. Could the specific African cultivator be categorized as peasant, or the Latin-American pastoralist? The fruitfulness of discussing such detailed classifications is questionable. When the core of the term has been identified, the borders drawn must be flexible to allow for interpretations, which in themselves include a dynamics. During the discussion, it also became increasingly clear that the specific historical situation must be taken into account. Rodney Hilton pointed at the essential elements in defining the English medieval peasant, but also made

clear that this definition was specific for a part of Europe, where the peasantry must be seen in the context of the medieval feudal society (Hilton 1975).

The concept of peasant will be used in this article in a very comprehensive sense, which includes those who raise crops or cattle, on a partly nonprofitable base, and are integrated in larger social structures. The definition includes peasantries in all societies where the production of foodstuffs requires the major part of the society's labor. It is debatable whether there could be peasants in societies where cultivators comprise a diminishing share of the population. Today in most countries outside the Western World, peasants continue to be tied to the soil and to the local community, with family, relatives and traditions, in a way that characterizes them as peasants. Also in a large part of Europe, there are still cultivators who live as traditional peasants. They live surrounded by their ancestors' history in houses, land, and tales and they are bound to their own farm by family-traditions. This should not be underestimated as a fact that for instance decides the course of contemporary talks on agriculture and world trade between Europe and the US.

Accordingly, the term peasant also has some relevance in today's society, and this is the explanation of why many languages have not developed the terminological difference found in English between peasant and farmer. However, the difference between peasant and farmer identifies an important historical change, and the peasant society is a purely historical concept for the Western World. Rural society should be regarded as a broader unit comprising, in addition to cultivators, craftsmen and rural industry. Rural society thus contains the seeds of proto-industrialism, and the concept is more relevant to today's conditions.

2. Historiography

To understand the discussion about the peasant and rural societies, it must be placed in a historiography, which both precedes and follows the postwar discussion. Rural society as a historical concept must be related to agricultural history, which mainly concerns agricultural production, but also includes other elements related to agriculture, such as politics and village communities. In rural history, the emphasis, formally speaking, is placed more on the societal aspect and in the case of agricultural history, more on the history of production and distribution. But since agricultural production is the basic activity of all peasants, in practice, rural history and agricultural history are parts of the same historiography. Rural history and agricultural history are an important part of general history, as the farming population for centuries was in the majority, but despite this, rural history and agricultural history emerged as specific disciplines relatively late.

2.1 The First Folk-life Studies

Scientific research into peasants and rural history in Europe began at the end of the nineteenth century. In many parts of Europe, i.e., Eastern Europe and Scandinavia, interest focused on the countries' own peasants. In the UK, research primarily focused on peasants in the colonies. In countries where agriculture played a dominating role, agricultural history was linked to the creation of national identity, demonstrated in national 'agricultural museums.' In Hungary, what is still one of the world's most important agricultural museums was founded in conjunction with the country's millennial celebration in 1898. National agricultural museums were also established in the Czech Republic and Denmark at the end of the nineteenth century.

In Eastern Europe, Scandinavia, and Germany, folk-life studies focused on the peasants who were regarded as the real heart of the nation. Later, these studies also played a prominent role under the name of ethnology or ethnography in France, Portugal, Ireland, Scotland, and other countries, but never in England. Folk-life research studied both spiritual and material culture, and described tools and houses together with folk-songs and riddles in peasant societies. A large knowledge-base was built up.

The scientific question that crystallized concerned regionality. Even if the original question was couched in terms of national identity, the answer increasingly proved the opposite. The cultural phenomena moved freely across borders, there were no obvious and given national borders in Europe. The Swede Sigurd Erixon played an important role, and a number of national ethnographic atlases, where the focus was on peasant society and its manifestations, were published. There were plans to publish a common European ethnographic atlas, but today these plans have been put on ice.

In the countries with colonies, above all the UK, the study of peasant societies outside Europe became increasingly popular at the end of the nineteenth century. Originally, these studies were part of the colonial administration, e.g., in the genre of studies of the Indian countryside, which the British Empire created as early as in the middle of the nineteenth century. Eventually social anthropology became a discipline in its own right, less and less connected with the colonial administration. In the twenty-first century it has a strong position in the Anglo Saxon world, not least in the US. Like European ethnography, anthropology was linked to the museums and the decades around the turn of the century were spent gathering data.

The goal of these studies was to understand the local community, in all its details but also its internal structure. The focus was on the individual village or region as an isolated entity. The level of detail could also be very high in the case of the material culture, but

the focus was often on the relationships between the people, e.g., family relationships. But even though the research concentrated on clarifying the internal structure of the local society, the studies gradually pointed to a different result. It was increasingly realized that the local society was integrated with, and subordinate to, larger social structures. This was one of the most important reasons why parts of the Anglo Saxon world of anthropology started using the term 'peasant' instead of 'people,' and it led to the above mentioned debate on peasant societies.

Early on, the combination of ethnology and anthropology resulted in impressive surveys. The German researcher Paul Leser, for example, published an authoritative survey in 1931 of different types of ploughs in different parts of the world (*Entstehung und Verbreitung des Pfluges*, Munster). Not long afterwards, Leser, who was Jewish, was forced to emigrate. Folk-life studies in Germany increasingly became a part of the nationalistic ideology in the 1930s, and was concentrated on studies about the spirit and 'soul' of the people.

2.2 Agricultural History in the Interwar Period

The US was still regarded by its inhabitants as an agricultural nation into the twentieth century. In the democratic and popular tradition that was this nation's identity, the history of agriculture played a role in the explanation of its progress and success, and agricultural history crystallized early into a discipline in its own right. The oldest national journal on the subject, *Agricultural History* (1927–), was founded in the US. From the very beginning, this journal contained articles about conditions outside the US, but it has focused mainly on American agricultural history. Initially, many of the articles discussed progress in agriculture at the end of the nineteenth century and the beginning of the twentieth century. A special genre consisted of articles about diaries kept by peasants.

In Europe, the first wave of interest in the history of agriculture, in ethnography and anthropology, focused on the immediate past. There were few attempts made to create a broader time perspective, as the discipline of history was still oriented towards the history of the State and the elite. Rural history developed in France under the influence of geography, where a dominating group of scholars favored all-embracing studies where every aspect of a region should be described, including historical aspects. With geography's starting-points in the land, these studies also touched on rural history.

The historian who succeeded in giving rural history a scientific basis was the Frenchman Marc Bloch in his *Les caractères originaux de l'histoire rurale française*, which was published in 1931 (Bloch 1966). This was based on a series of lectures he had held in Oslo in 1929 at a research institute, which had been established to promote and carry on Scandinavian folk-life

studies. Here the different threads meet. In the words of the American agrarian historian Richard Herr, Bloch was able to provide 'the kind of insights that would spark the imagination of other historians' (Herr 1993, pp. 4–5). In a subsequent study of European feudalism, Bloch explained how a rural society is part of a large social structure (Bloch 1961, in French 1939–40). He thus anticipated the discussion about peasant societies during the postwar period.

Bloch's work still provides inspiration and guidelines in a number of areas: the role of the village community, peasant uprisings, the connections between technology and social change, etc. But years passed before his books were considered to be important. General acceptance did not come until after World War II. In part, this was a result of the myths created about Bloch after he had joined the French Resistance to fight the Germans and was executed in 1944.

2.3 Agricultural History's Breakthrough after World War II

The reason for the rise in appreciation of Bloch's work should, however, be explained in terms of the large changes that occurred in the study of rural societies and agricultural history. During the 10-year period following the end of World War II agricultural history became a discipline in its own right in Western Europe. Departments of Agricultural History were established in several European countries: in the Netherlands at the agricultural university in *Wageningen*, in Germany at the agricultural university in *Stuttgart* and in the UK at the Faculty of Agriculture at *Reading University*.

National journals were started up in Europe: *The Agricultural History Review* (1953–) in the UK, *Historia Agrariae* (1953–) in the Netherlands, *Zeitschrift für Agrargeschichte und Agrarsoziologie* (ZAA) (1953–) in Germany, *Bol og by* (1956–) in Denmark, *Rivista di storia dell' agricoltura* (1960–) in Italy and *Études rurales* (1961–) in France. In time, the breakthrough for agricultural history resulted in national synthesis covering several volumes. In the UK, a huge project in eight volumes was started in 1967, *The Agrarian History of England and Wales*. This work has yet to be completed. The German synthesis, *Deutsche Agrargeschichte*, consists of six volumes and was published between 1962 and 1984. In France, *Histoire de la France rurale* was published in four volumes between 1975 and 1978. Although the French volumes emphasise rural history in the title, there is no major difference between this and the other national works. In the German, two volumes are devoted to purely social questions, i.e., legal questions and peasants as a social category.

This wave of research resulted in a focus on the long-term change, and not least on the Middle Ages. At the beginning of the 1960s, two important works

were published. One of these was Georges Duby's *L'économie rurale et la vie des campagnes dans l'Occident médiéval*, published in 1962, which was a study in the tradition of Bloch (in English 1968). The following year, 1963, saw the publication of an English translation of a study published in Dutch some years earlier. Slicher van Bath's *The Agrarian History of Western Europe AD 500–1850*.

During the postwar period the agricultural crisis in the late Middle Ages became a central field of research. This economic decline had been observed before World War II (i.e., for Germany, Abel 1980). The discovery was theoretically significant since it showed that the development of production had not always been positive. Another important theoretical change was that agriculture was seen as a dynamic sector in medieval Europe, which partly rejected earlier theories about the countryside as having a restraining effect on economic development. The aftermath of World War II continued to leave its mark to some extent. Slicher van Bath, who had built up the Department of Agrarian History at the University of Agricultural Sciences in Wageningen in the Netherlands, mainly collaborated with Anglo Saxon researchers and not with the German, e.g., at the agricultural university in Stuttgart-Hohenheim. The reason for this was that Gunter Franz, who had built up the Department of Agricultural History in Stuttgart, was not only a leading expert on the German Peasant War, but also had been an active Nazi. However, the journal founded by Franz, *ZAA*, published early on historiographical surveys of agricultural history in Europe. These surveys were written by Duby, Postan, and other leading European agrarian historians. It must also be stated that several leading agrarian historians in Germany during the 1930s never became engaged in the Nazi movement, for instance, Wilhelm Abel and Friedrich Lütge.

2.4 The Transformation of Folk-life Studies after World War II

The discussion about the concept of 'peasant' resulted in a number of studies of peasant and rural societies. These include the classic studies made by Oscar Lewis in Mexico and India. Daniel Thorner's studies of peasants in India are another example (a bibliography in: *Peasants in History: Essays in Honour of Daniel Thorner*, Hobsbawm (ed.) 1980). Several studies were also carried out in Europe, often by American researchers who used anthropological methods to study villages in Southern Europe. They were somewhat surprised to meet an entirely different type of cultivator from those they usually met in the US. It was still peasants and not farmers who dominate the European villages. The classic studies here include those by Julian A. Pitt-Rivers, who studied a Spanish village (1954), and by Joel Halpern, who studied a Serb village (1958).

In anthropological research, the large databases, e.g., the Human Relations Area Field (HRAF) in Yale has been gathering information on several hundred cultures since the 1930s. But the previous focus in anthropological research on material cultural products has weakened. True, encyclopedic studies were still being made, for example, by the Frenchman Leroi-Gourhan (1943–5), but this was more and more pushed into the background. Instead, it was the social structure that attracted increasing attention, and this is noticeable not least in the discussion about peasant societies. It was still the hidden patterns that research wanted to be clarified, but now as part-cultures subordinate to the principal culture. Clifford Geertz, had made an important description of the history of agrarian technology in Indonesia (*Agricultural Revolution* 1964), became even more influential as a father of the concept 'thick description,' which became a leading method in anthropology (see articles in Geertz 1973).

In Eastern Europe, folk-life studies retained and, to some extent, strengthened their role when the Socialist people's republics were established. Research into 'the people' was emphasized as one of the main tasks of historical research. At the same time, contacts with the West were broken off. An example is how seldom the German researchers in the East and West referred to each other, even though they often made research about the same subjects.

Some contacts were however upheld. *Association International des Musées d'Agriculture (AIMA)* gradually became the meeting place between East and West for the study of rural society. AIMA was an association of agricultural museums all over Europe as well as in the US, which was formally under the jurisdiction of UNESCO. The association was formed in 1974 and its meetings were held alternately in Eastern and Western Europe (or the US). Many of the questions discussed were classic in European ethnography, e.g., the history of the plow. After the Communist collapse, this association has had a difficult time.

2.5 Reasons for the Breakthrough after World War II

There are many underlying reasons for the breakthrough of rural history in the 1950s. In the Netherlands, one of the reasons given for the establishment of a Department of Agricultural History was that the severe food shortage at the end of World War II illustrated the importance of agriculture. In all social sciences the American influence increased after World War II, not the least in sociology of agriculture and in studies of non-European peasants. This influence may also have had an impact on agricultural history.

A factor, which can hardly be underestimated, was the increased political importance of peasants on a worldwide scale and in conjunction with colonies

attaining independence, but the immediate conclusion was not that scholars regarded the peasants as decisive actors in history.

Peasants and rural societies were identified as essential elements of the social structure. Initially, the new research focused on concepts and ideas from the earliest period of folk-life studies in Europe, and emphasized that peasant culture had filtered down to the peasants from the elite. Villagers had taken over and simplified traditions from the towns or from the elite. The goal of the peasants was to imitate the leaders of society. The ideological basis for this interpretation was that society's leaders were considered to represent a higher form of civilization. The interpretation was made in more or less explicit forms by almost all the scholars participating in the discussion after World War II and in particular by George Foster (1967). Robert Redfield (1956) distinguishes between a great tradition and a little tradition, between the classical, learned elite culture, and the peasant tradition. He emphasizes that a mutual exchange takes place, where also the elite draw inspiration from below.

The view of the conservative peasant society which was unwilling to accept changes that upset traditions is similar to what is sometimes called 'the dumb peasant theory.' This implied that peasants had to be forced to develop, and this assumption guided much of the Western World's relations with the Third World throughout the 1950s and 1960s.

2.6 New Interpretations in the 1970s and 1980s

Beginning in the 1970s, studies of peasants and rural societies increased in number and became more diversified. Two partly connected phenomena began to change the picture. One was the Marxist challenge in the academic world, the other was the successful peasant uprisings in different parts of the world, not least the civil war in Vietnam. These two phenomena challenged the old thought structures, but did not lead to a new hegemony. Instead, after the major theoretical battles in the 1970s, the field was left open to a large number of different theories. This can be compared with the change undergone by rural sociology at the same time. A survey from 1990 shows that what the authors call 'the new rural sociology' from the 1970s and 1980s was characterized by a large number of interpretations (Buttel et al. 1990).

The common question with which many of the new interpretation struggled was the relationship between actors and structure, where the peasants were increasingly regarded as real actors in the historical process. One expression of this new and deeper interest in peasant studies was the *Journal of Peasant Studies* (1974–). In its editorial policy, it was emphasized that the journal would be concerned with political economy

and that it would attempt to understand the role of the peasants, especially outside Europe and North America.

At the same time we also see a growing interest for rural history in the third world, and for instance, a journal on the subject was founded in India: *History of Agriculture* (1973–).

The role of class conflicts became more important, which at times resulted in very detailed analyses of the social structure of the countryside. Studies of peasant revolts and peasant uprisings were developed into a special genre with a series of studies. Searches in international databases show that there is an interesting geographical distribution of the studies. Most of the studies of peasant revolts outside Europe concern Asia (India, China, Japan, South East Asia, and Indonesia) or Latin America (Mexico, El Salvador, Bolivia, and Brazil). Studies concerning Africa, on the other hand, began early on to be more focused on the environment, while studies of peasant revolts are less common.

An example of this new orientation is the rapidly growing interest in 'Maroon societies.' The fact that slaves in Latin America as well as in the American South were able to break free and establish societies, which in some cases were able to survive for hundreds of years partly outside the control of the authorities, added a new dimension to peasant society. The first comprehensive study of Maroon societies as a specific form of peasant societies in 1970s was followed by many more (Prize 1996). This history from below was also applied in other areas.

In the European research about long-term changes new interpretations emerged. The dominating researchers had initially been supporters of Malthusian interpretations, but other interpretations gradually began to be given greater emphasis. One example of this is the class perspective introduced by Guy Bois (1976) into the interpretation of the agrarian crisis in the late Middle Ages.

The older type of studies of material culture continued, not least in the exchange between East European and West European researchers in classic folk-life research. In Denmark, the journal *Tools & Tillage* was established in 1971 and became the leading international journal dealing with the development of agriculture technology in peasant societies.

2.7 Diversification at the End of the Century

The late twentieth century has seen a gradually growing interest in rural and agricultural history. New journals have been started up, including *Rural History* (1990–) in the UK, *Noticiario de historia agraria* (1991–) in Spain, *Skrifter om skogs- och lantbruks-historia* (1991–) in Sweden, and *Histoire et sociétés rurales* (1994–) in France.

There are new elements in this growing interest. One that is very important is the interest in environmental questions. This has had an impact on agricultural history not least in the US in the form of studies comparing how Indians and Europeans used the environment in a social context (i.e., Merchant 1989). Specialist journals have also been established, the most important of which is *Environmental History* (1989–) in the US, formed by merging two journals with the same orientation, which had been published since the 1970s. The issues dealt with have concerned sustainability in a long-term perspective in relation to current problems such as soil erosion, salinization, etc.

Interest in popular culture and social structure is increasing, and one example is the research group around Jan Peters (Peters 1997). This group also represents a successful wedding between East and West in Germany in the late twentieth century. Another strong orientation, although not only in the study of rural and peasant societies, is gender studies. Technology research has also been revived although here, more specific questions are being raised concerning the connection between technological and social change.

3. Theories and Methods—a Summary

When the question of the definition of peasants and peasant societies was raised after World War II, it proved to be both fruitful as well as inspirational to further research. The connection between peasants and social structure was brought out more clearly. However, this was only one step in a long development process involving research, and rural and agricultural history. At the end of the nineteenth century and beginning of the twentieth century, researchers concentrated on gathering material. In Europe, individual cultural elements were registered, and outside Europe whole peoples and their characteristics were dealt with. Theories about isolated nations and communities were proposed, and abandoned.

In the 1950s larger structures were identified. In anthropology, peasant societies were regarded as being a part of larger society, and in history the long waves came into focus of the research. During a following phase, which began in the 1970s, research became increasingly diversified. Much of the research emphasized the capacity of peasants to take independent action, and new fields of research, such as environmental questions and gender research, were opened up. This eventually resulted in a new wave of interest about the subject at the turn of the twenty-first century.

Peasants in Anthropology

Peasants are small-scale agriculturalists who use simple technology such as hand tools, human labor, animal power, and possibly light machinery. The household is the basic unit of production and consumption. While some peasants grow crops or raise animals for markets, they usually consume most of what they produce and thus differ from farmers who produce primarily cash crops. Also, peasants typically exist in subordinate political and economic relationships with other sectors of society who receive surplus products and labor from them. From the rise of civilizations based on non-mechanized agriculture until the widespread use of modern industrial farming, peasants in rural areas have provided much of the food and other basic material resources consumed in urban society. Furthermore, peasants have provided recruits for armies throughout history, and until fairly recent times in developed nations, cities typically had high death rates relative to birth rates and thus had to be replenished by peasants migrating from rural areas. Indeed, most of the rapid growth in world population in the nineteenth and twentieth centuries was due to continued high birth rates among peasants, and correspondingly lowered death rates due to the spread of modern medicine and public health.

1. *Peasants in the History of Anthropology*

From its modern beginnings in the 1800s until the early to mid-twentieth century, anthropology focused largely on foraging, tribal, and chiefdom societies. It was not until after World War II that peasant communities became a major object of anthropological research. This shift of interest by anthropologists toward peasant communities was due to changing global conditions. Foraging and tribal societies were disappearing at ever increasing rates, and in addition to this, following the War, peasants emerged on the world stage as major political actors in the context of the Cold War. Within this global struggle between the so-called 'First World' of capitalist societies and the 'Second World' dominated by the communist Soviet Union and China, many underdeveloped 'Third World' countries were inhabited mainly by rapidly growing peasant populations. The political significance of these nations grew as concern mounted as to whether their peasant populations would veer toward communism or capitalism. Since the poverty of peasant communities was seen as a major inducement for them to turn to communism, promotion of economic development in rural areas of the 'Third World' became a priority of US foreign policy. In this geopolitical context, the anthropology of peasant communities flourished from the 1950s until approaching the end of the Cold War in the early 1990s

(Kearney 1996). Much of this work was applied anthropology concerned with the improvement of agriculture, health, and education in peasant communities.

2. *Anthropological Approaches to Peasants*

A distinctive feature of anthropology is that it seeks to study and comprehend all of the major components of a community and how they are integrated. Ideally, this comprehensive method begins with examination of the physical environment of the community and how its inhabitants adapt to that environment with technology and a distinctive division of labor with which they produce food, shelter, and amenities. These features of the environment—technology, labor, and the material products of labor—are parts of a community's infrastructure, upon which are based an immaterial superstructure that comprises a corresponding patterning of social organization, politics, class positions and relations, gender identities, religion, world view, etc. Ideally, a robust anthropological treatment of a peasant community examines all of these material and immaterial components of a community and how they are interrelated. Furthermore, since peasants, by definition, typically exist within and are shaped by relations of unequal economic exchange with non-peasant communities, a complete anthropological study of a peasant community would also examine this dimension. In practice, however, few anthropologists attain such comprehensiveness. Instead, most anthropologists who study peasant societies tend to concentrate on either superstructural or infrastructural features of a local community, or seek a more comprehensive treatment by focusing on selected features of each. Similarly, anthropological studies vary considerably in the degrees to which and the ways in which they consider how peasant communities are related to non-peasants. These differing approaches and foci can be illustrated in the work of four contrasting anthropologists.

2.1 *Redfield and the 'Folk–Urban Continuum'*

According to Robert Redfield (1941), peasant communities are a kind of folk society that exists on a 'folk–urban continuum,' which has both geographic and historic dimensions. Cities represent the modern urban end of the continuum and small, isolated non-agrarian indigenous societies are the extreme traditional folk end, with peasant communities near the traditional end. Redfield saw the history of traditional societies as shaped mainly by the spread of modern features of technology, social organization, family, kinship, values, and world view outward from cities at

the urban end of the continuum toward the folk end, in a process of modernization or development. This diffusion of the traits of modernity, especially modern values and world view, would proceed faster were it not for barriers to their acceptance in the traditional culture. This model became important in programs of applied anthropology that sought to identify and overcome cultural barriers to modernization in peasant communities, which were defined as underdeveloped, that is, as waiting to shed their traditional cultures by becoming fully incorporated into the modern national culture, economy, and political system of their nation. This approach to economic, social, and political development in peasant communities became important in American applied anthropology during the Cold War as an alternative to socialist and communist paths of development.

2.2 Foster and the 'Image of Limited Good'

Based on long-term intensive fieldwork on the economics, social organization, and culture of a Mexican peasant community, George Foster (1979) developed a model of world view to explain peasant economic and social behavior. This model, 'The Image of Limited Good', in the superstructure of peasant society, is based on economic realities in the infrastructure. Foster notes that land, markets, employment, and other sources of income exist in limited amounts in local peasant economies and therefore there is great competition for such scarce resources and economic opportunities. There are rarely enough of the basic material resources to satisfy everyone's needs and wants. In this situation, peasant ethics and morality are based on the idea that the best accommodation to this situation of Limited Good is for all members of the community to have an equal share of different forms of Good, e.g., food, wealth, affection. Therefore, if someone gets more than their fair share of some form of Good, then, according to the logic of Limited Good thinking, someone else must get less than their fair share. Foster says that this realistic perception of material realities shapes peasant world view in general, which is expressed as envy, fatalism, individualism, fear of witchcraft, and also principles of folk medicine, proverbs, and basic features of social organization and economic behavior, all of which are barriers to development.

2.3 Wolf and the 'Closed Corporate Peasant Community'

Whereas anthropologists working with a modernization perspective, such as Redfield and Foster, focused on barriers in traditional peasant society to the acceptance of modern cultural traits coming from developed urban areas, other anthropologists working

with Marxist concepts examined the opposite process, that is, how unequal market relations, cheaply remunerated labor, interest payments, taxes, and tribute tend to drain economic value from peasant communities. Working with this perspective, Eric Wolf (1966) developed the structural model of the 'closed corporate peasant community' to demonstrate how, contrary to Redfield, peasants were not isolated from urban society, but instead formed much of its economic base. He explored mechanisms of value extraction and how peasants attempted to minimize it by seeking to 'close themselves off' and defend themselves from exploitive outsiders. Wolf notes that the household organization of production, and the culture of envy and suspicion that Foster and others describe, tend to promote individualism and a lack of community solidarity. These traits led Karl Marx to characterize peasants as like 'potatoes in a sack,' that is, unable to organize in their own self interests. But anthropologists like Wolf who were working with a political economy orientation have also been interested in the revolutionary potential of peasants. Indeed, in the twentieth century, some of the major armed conflicts such as the Mexican, Russian, and Chinese Revolutions, and the Vietnam War, have been characterized as peasant wars (Wolf 1969) in which peasant communities sought to gain political and economic independence from non-peasant exploiters.

2.4 Meillassoux and 'The Articulation of Modes of Production'

Since the 1960s anthropologists have become increasingly concerned with migration from peasant communities. Claude Meillassoux (1981), who, like Wolf, also worked in the Marxist tradition, examined how, through circular migration, rural people who were unable to make a complete living as peasants could supplement their income by migrating to seek temporary work as proletarians, thus articulating the peasant and the capitalist modes of production. This situation is seen as a benefit to the modern sector because it shifts costs for the biological and social reproduction of workers to peasant communities. Also, because such peasant workers produce part of their own food and other necessities on their own land, they can accept lower wages than fully proletarianized workers, who need more cash to buy their basic necessities. Thus, whereas the modernization approach of Redfield, Foster, and others predicted that migration would hasten the development of peasant communities, the articulation perspective revealed how such partial proletarianization in some ways perpetuates peasant ways of life in the countryside. Nagengast (1991) shows how this was true even in a socialist country, such as communist Poland, that had strong national policies for full proletarianization and

modernization of the countryside. Such conditions of partial proletarianization raise questions about the basic class nature of such peasant workers and worker peasants, and what are the most appropriate political projects to defend their class interests.

3. Economic Development, Global Change, and The Future of Peasants

Applied anthropology in the Redfield and Foster tradition sees peasant social organization, conservative culture, and world view as barriers to the acceptance of the social and cultural traits of modernity that are essential to economic development. Foster argues that the economic realities that peasants face dispose them to be skeptical and fatalistic about possibilities for personal and especially cooperative efforts to overcome their poverty. According to this analysis, the role of applied anthropology is to understand these social and cultural dynamics of peasant communities and demonstrate alternatives to them. In contrast, applied anthropology in the Marxist tradition, as exemplified by the work of Wolf and Meillassoux, and also by dependency theory and world system theory, pays more attention to structural conditions that keep peasants in politically and economically subordinate positions so that surplus can be extracted from them and transferred to other sectors of the national and world economy, thus maintaining peasants in conditions of *de-development*. Accordingly, applied anthropology for peasant communities in this tradition is concerned with ending such unequal exchange so that de-developed nations and their peasant communities can retain more of their wealth for their own development.

Currently, increased migration between rural communities and cities and across national borders, and the social networks and complex livelihoods that result from it, have largely obliterated the cultural, social, and economic distinctions between rural and urban areas upon which the persistence of peasants depend. Also, as the rates increase at which supposed peasants migrate in and out of a variety of economic niches—ranging from subsistence farming, to wage labor, to the informal economy, etc.—so do the volume, velocity, and diversity of commodities and information that they consume also increase. These demographic, occupational, and cultural trends towards increased mobility and differentiation thus call into question the geographic, economic, social, and cultural basis of contemporary peasant society and culture (see Kearney 1996). Indeed, peasant societies that, until recently, were the most populous type in world history seem to be rapidly disappearing.

Pecuniary Issues in Medical Services: Ethical Aspects

The medical services a person receives depend not only on the patients' health status, the benefits covered by public or private health plans, and the latest developments in medical knowledge but also on the financial incentives offered to doctors that encourage them to use or withhold such services. This may compromise the physicians' loyalty to patients or the exercise of independent judgment on their patients' behalf (Rodwin 1993). Ethical problems arising from financial incentives in the health care system are as old as modern medicine. But their nature is changing along with the transformation that medical care is undergoing in the industrialized countries of the west.

1. Patient-Physician Relationship

At the core of a health care system there is still the patient-physician relationship. In their relationship with physicians patients are people seeking help. That results in this relationship's asymmetry, one that is

unavoidable to a certain extent. Patients can have neither the technical expertise needed to provide specific medical services nor the knowledge and skill to determine what care is needed, nor are they able to coordinate and negotiate the complexities of a highly specialized medical system to make sure that the services needed are actually provided. Patients can be very inhibited by disease, by too high or too low an age, by pain, anxieties, and worries; that means they are in special need of protection. Their vulnerability is intensified even more when they expose their bodies and reveal their most intimate histories, physical and otherwise. Even if patients participate in medical decision-making, they still depend on the physician's advice and need to trust him or her. All the concepts designed to guide medical care, whose ability to function depends on patients successfully playing the role of a 'critical customer,' ignore this asymmetry and the ill person's resulting need for protection.

In modern medicine, the physician-patient relationship is assuming ever clearer forms of a production process based on a division of labor. The patient, as a suffering subject, is at the same time a 'workpiece object' and—to different degrees—a co-producer. That means he or she is directly impacted by rationalization and bureaucratization processes in the health system, and that any changes can set the course for the patient's fears and hopes, pain and comfort, life and death.

Medical services are so complex that legal norms alone cannot protect the sick from unnecessarily suffering or even dying due to mistakes arising from the physician's lack of loyalty. Or to put it another way: a large part of successful physician-patient relationships is based not on (undoubtedly necessary but inadequate) statutory norms but on ethical ones that are internalized in the physician's professional habitus.

2. *Ethics and Institutional Structures*

Most philosophers, including bioethicists, have so far overlooked or at least underestimated the nexus between acts and the institutions increasingly in control of these acts. As a result, they overlook the fact that the 'production' of medical services is not only a work process but also a socialization or learning process, the ethical values of which are learned, reproduced and also modified and repressed. The moral-molding character of the institutions must be assessed as much stronger and durable than that of professional ethicists. This nexus can be approached with simple behavioral assumptions of the kind proposed by Freidson (1970):

First, (...) whatever motives, values, or knowledge people have come into contact with and have 'internalized,' they do

not guide the behavior of most individuals unless they are continually reinforced by their social environment.

Second, (...) the environment can, by reinforcement, lead people to forsake one set of motives, values, or knowledge in favor of another.

And third, given the first two, the average behavior of an aggregate of individuals can be predicted more successfully by reference to the pressures of the environment than by reference to the motives, values and knowledge they had before entering the social environment. The basis of prediction is from the requirements for social 'survival' posed by the social environment and refers to the functional adaptations of the aggregate of individuals who survive. Prediction is, of course, statistically inapplicable to any individual except as a probability value.

The more the power of institutional structures to determine behavior increases, the more significant ethical 'predecisions' embedded in the structure of medical institutions become.

3. *Financial 'Conflicts of Interest' (CoI)*

It is in this sense that the notion of '*conflicts of interest*' has come into use for discussion of the ethical aspects of pecuniary issues in medical services (Spece et al. 1996). It does not mean a subjective, 'inner' conflict that arises when interests of equal standing are weighed but 'a set of conditions in which professional judgment concerning a *primary interest* (such as a patient's welfare ...) tends to be unduly influenced by a *secondary interest* (such as financial gain)' (Thompson 1993). That is the case if the loyalty to patients and/or the independence of professional judgment is compromised (Rodwin 1993).

Primary interests we can define as the ethics patients expect of loyal physicians in western industrialized countries:

- (a) to be loyal to patients,
- (b) to act solely in the patient's interest,
- (c) to make their patients' welfare their first consideration, even when their own financial interests are opposed,
- (d) to keep patient information confidential.

When the ill turn to physicians, they are confident that the same physician will act in trust as their agent and not primarily in order to enhance their income or to perform as agents for third parties. Secondary interests such as a physician's financial gain and his or her professional career are not illegitimate but should be prevented from dominating. Unlike the situation with ethical dilemmas, only one side of the conflicting interests has a claim to priority. This asymmetry between interests is a distinctive characteristic of the concept (Thompson 1993). Conflicts of interests are not an expression of misguided behavior but of *latent* misguided behavior that is built into organizations' systems of incentives and sanctions. They can influence action, but they are not acts and they do not ensure disloyalty (Rodwin 1993).

4. *Transformation of the Health Systems*

In most western industrialized countries the changing structural context is distinguished by shifts in power from the providers to the payers of medical care. This is expressed in the enforcement of new, prospective forms of financing with which expenditures can be limited. Therefore, the financial risk of treatment is increasingly shifting to the providers of medical services. That means their financial success depends on the extent to which the resources consumed by diagnosis and treatment are lower than the fixed capitation fees, budgets, DRGs (diagnosis-related groups: coding in which hospital procedures are rated in terms of cost and the intensity of services delivered, regardless of the cost to the hospital to provide that service) or flat rates. Since every service was paid for or all costs reimbursed with the traditional, retrospective methods of financing, that led for the most part to incentives to increase services. With prospective payment systems, *incentives to decrease* services now predominate, and that creates specific conflicts of interests.

The pressure of limited possibilities to expand is now intensifying competition among the providers of medical services. The main parameter in this respect is minimization of operational costs. Since they are largely determined by physicians' decisions, the ability to control and steer the physician-patient relationship becomes the pivotal point of economic success.

The problem has two elements: first, the financial incentive that rewards certain medical decisions and penalizes others and, second, the degree of inevitability that competition and/or management can compel. That gives rise to different combinations of direct influence on physician-patient relationships via 'micromanagement' and indirect influence via financial incentives. As a result, the push-pull effects of financial incentives for physicians become ever harder to avoid.

5. *Micromanaged Care—Decisions Made at a Distance*

Providers exposed to the pressures of prospective financing have developed an incalculable number of management tools to control the physician-patient relationship, e.g. the use of medical protocols to assess clinical decisions, retrospective utilization reviews, systems of prospective authorization of services, the introduction of primary care physicians as gatekeepers to control referrals to specialists and hospitals, and many other devices. The crucial factor is that important medical decisions tend to be removed from the sphere of direct contact between the patient and physician and transferred to a management.

Here we are no longer dealing only with a conflict between the precept of loyalty to the patient and the interests of the organization. Rather the fact that a

management makes decisions in the absence of the sick person is already a contributory factor that changes the substance of the decisions. The moral nature of such 'decisions made at a distance' is different from decisions made face to face with the other person (Bauman 1989). If a management is to make relevant medical decisions, then questions of suffering and pain, misfortune and hope, life and death must first be turned into indicators, measurable values, and formalized norms, and thus rendered bureaucratically 'banal.' The sick individual's chances of finding empathetic loyalty are thus minimized.

6. *Monetary Incentives*

Monetary incentives are demands on the physician to individually maximize utility: 'if you choose option A instead of B in your clinical decisions, you will be rewarded/penalized with a higher/lower income.' Over and beyond the direct impact on income, the incentives also assume a normative character (in terms of both medicine and ethics): if certain decision-related options are financially rewarded, they are often considered to be medically appropriate and ethically sound.

The forms of prospective payment are multifarious. In the view of their advocates they lead:

- (a) to careful handling of tight resources,
- (b) to less overuse of medical services,
- (c) to a better quality of services, since, after all, part of the financial morbidity risk is imposed on the physician,
- (d) to structural changes and integration in a way that maintains the health of the insured population through disease prevention and health promotion,
- (e) to innovations resulting in measurable improvements in patient satisfaction, and
- (f) they permit this without interfering with the physicians' freedom to decide, i.e. without creating red tape, simply by changing the conditions in which decisions are made.

Critics counter that conflicts of interests resulting from incentives to decrease services (a) could lead to clinically inappropriate decisions and (b) potentially harm the ethical precept of a physician's loyalty to his or her patients, who expect, after all, an independent clinical appraisal in their interest.

(a) The physicians' clinical judgement will be biased and loyalty to the sick person may be at stake when certain options involving clinical decisions are financially rewarded or sanctioned depending on their cost. For example, in the case of capitation and fund holding, the income of the primary physician drops if he or she refers patients to a specialist, prescribes costly drugs, admits them to hospital, or calls for expensive diagnostic procedures. When individual physicians or small group practices assume the insurance risk in this way, without their number of patients being large enough to compensate for the risk,

patients in need of extensive treatment become a threat to their vital interests.

Incentives for underservice should also be avoided since they cannot be an appropriate response to the wrong turns taken by care in the western industrialized countries. For one, there may be overuse in countries like the USA, Germany, or Canada, but at the same time there is also underuse and misuse. For another, such incentives may reduce the extent of certain services, but they cannot substantially alter the ratio of necessary services to unnecessary and harmful ones (Brook and Kosecoff 1988). Since, namely, the pecuniary incentive is blind with respect to what is medically proper, beneficial services have, in principle, the same chance of being reduced or expanded as superfluous and harmful ones. Only with respect to one type of monetary incentives does there appear to be acquiescent agreement: when extra earnings are linked to clearly defined and transparent, positive goals (e.g. increasing participation in screenings, house calls, better quality indicators), there will be hardly any possibility for a conflict of interests and therefore no risk to the patient.

(b) From an ethical point of view such monetary incentives are an implicit rejection of the sick persons' expectation that the physician should be their agent. If, namely, medical decisions were only made with a view to the patient's needs and in keeping with the state of the medical art (as every patient expects and professional ethics prescribe), the type of financing would be of absolutely no importance for the physician's services-related conduct. Regardless of whether a physician receives a fixed salary or payment based on capitation, the services profile would remain the same in every case. The effectiveness of monetary incentives thus stands or falls with the physicians' readiness to violate their clinical judgment and the ethical precept of loyalty to the patient and instead pursue income-related interests (or those of their organization). If they do not do so, all attempts at monetary steering are senseless.

(c) Indirect steering of the patient-physician relationship via monetary incentives to decrease services is not an alternative to the so-called 'bureaucratic model' but tends to bring about such a model. Producers of highly complex services like physicians always have more information at their disposal than the controlling management of the insurance company or the provider organization. So they can use it to manipulate the system ('gaming the system'). Ironically, strong incentives at the level of the physician-patient relationship, with its intimidating implications, produce a spiral of attempts by the physicians to outwit them and by efforts on the part of the other side to increasingly restrict the opportunities to do so, with the result of more regulation and less freedom for doctors and patients alike.

Under the pressure of economic competition, physician-patient relationships thus potentially become

part of an organizational machine. The ethical consequence thereof has been formulated by an American physician as follows, 'I imagine that every doctor in private practice can on occasion think of a patient as a dollar amount couched within a symptom, but I also imagine that doctors regularly pull back from such thinking by virtue of their education and morals. The dangers here are the institutionalization of the impulse to greed by the corporation and the individual physician's subsequent removal from personal responsibility for carrying out the actions that follow from that impulse' (Bock 1988).

The conflict between the 'two cultures' (McArthur and Moore 1997) or between the ethical codes of the profession and those of business is decided in this context in favor of the latter's dominance. With the help of a comprehensive set of tools, including financial incentives, the physician-patient relationship is squeezed into a system whose goal—profitability—is a purely quantitative one. No corporation can earn too much money, its costs can never be 'too low.' The tools of monetary incentives can signal 'more or less,' but not an objective or human criterion for 'enough'; nor can they signal the point at which the physician has to stop pursuing his or the health plan's income interests. So far it has not been possible to counter such boundless systems with any effective controls oriented to protection of the individual patient. In spite of efforts to establish monitoring systems like the HEDIS quality indicators in the US there is no practical system for externally monitoring (e.g. by public agencies) all 'the subtle ways in which providers, struggling to survive market competition, may stint on services' (Relman 1993).

7. The Trust Problem

Rodwin (1993) has written: 'In asking physicians to consider their own interest in deciding how to act, we alter the attitude we want physicians ideally to have. For if physicians act intuitively to promote their patients' interests, we will worry less that they will behave inappropriately. But if their motivation is primarily self-interest, we will want their behavior to be monitored more carefully' (p. 153). As already shown, financial incentives can only modify physicians' behavior in the intended sense when they act in their own income-related interest. That has to collide with the patient's expectation that the physician should place the patient's welfare over his own interests.

Not only is trust at stake but also a precondition for effective medicine. Interpersonal trust is a prerequisite, for example, for the patient's willingness: to reveal potentially stigmatizing information about health-related behavior (substance use, sexual practices, etc.), to describe personal feelings and thoughts necessary to differentiate mental from physical disorders, and to

accept treatment practices or prescribed changes in personal behavior that are difficult, painful, or risky (Mechanic and Schlesinger 1996).

It is not only the trust of the individual patient that is at risk. The trust of any and all in society to have a good chance of finding a loyal physician in case of need is a 'public good' and an element of everybody's standard of living. Public goods are never realized in ideal fashion. But there are respective critical limits. For instance, despite everyday violations we still think of the public good 'trust in traffic safety' as being assured, for otherwise we would never get into a car again. It would undoubtedly be destroyed if we had to expect, say, that 10 percent of road users would no longer stop when the light turns red. The public good known as trust would be invalidated as a result. Today competing business enterprises enforce their corporate strategies at the sick bed through the micromanagement of care, financial incentives to decrease services and sanctions, that increases the risk of 'ethical externalities' and thus of the 'social costs of business enterprises' in medicine.

8. Remedies

When making economic decisions, people will presumably choose the alternative that best serves their interests. But, as economist Amartya Sen points out, before they can do this, they have to make another choice. They must choose to frame their decisions as economic ones that are based on self-interest vs. moral ones that are based on concern for 'what is right.' Such decisions are what most people expect from family, friends and—specifically modified according to the ethical codes of the profession—their trustees like doctors and nurses (Schwartz 1994).

As shown, institutional developments are subjecting physicians to an economic framework of decision-making with growing effectiveness. Not only that, as socialization agencies institutions are seeing to it that the professional code of ethics is already being usurped by superimposed economic considerations. That is why, at the turn of the twenty-first century, people are starting to realize that the patient's welfare must no longer depend on whether a physician is able to resist financial incentives and to ignore or submerge his or her economic interest in order to act in the patients' interest. Society has to find an answer to the principle ethical question of whether the health and life of a patient seeking help is to be decided primarily within an economic framework, and the answer does not have to be expressed solely in the individual physician's conscience but also in the structure of the institutions. There are no patent solutions here. While in some west European countries there is hardly any consciousness of the problem posed by conflicts of interests yet, a public debate about the steps to be taken toward a solution has begun in the United States (cf. biography). Consideration is being given to a broad range of

possibilities. One group of proposals has in common that they would like to cap expenditures at the middle or overall social level by way of budgets, while individual physicians are to be paid a fixed salary (possibly supplemented by financial incentives tied to positive targets like outcomes and patient satisfaction). Overuse, underuse, and misuse of medical services should be prevented by supportive management as opposed to controlling and sanctioning management. Others would like to defuse the prospective payment systems, e.g. financial risk or gain should be limited, financial incentives should not directly reward decreased use of services unless there is specific evidence thereof and monitoring for underuse. Other types of safeguards proposed to protect patients are the disclosure of financial incentives, public review boards, creating independent organizations to certify quality measures, appeals boards to review cases of denied care for reasons of costs, the expansion of individual and collective patients' rights, and the strengthening of consumer organizations.

Pedagogical Reform Movement, History of

1. History of the Concept

Theories on educational reform have been current since Greco–Roman times, in all three directions of reforms related to school, life, and society. Reform movements in the Middle Ages initially occurred on the basis of religious motives, above all where deviations from church doctrines were associated with an alternative practice. Heresy always suggested new education, because the divergences from the main doctrine picked out alternative forms of salvation as a central theme, to which the life of an own group had to be adapted. Education was not centered on children and youngsters, but it focused on religious and social renewal. It was envisaged that the ‘new’ education would bring about ‘new people,’ a central theme which was developed in Baroque didactics into a program of holistic renewal of mankind. Proofs of this theme can be found in many contexts right up to the pedagogical reform of the twentieth century, in this respect ever more closely related to the mythology and cult of ‘the child’ (Boas 1990). The original sacred theme was continuously secularized, without weakening the appertaining religious power. The division of education and religion had shifted Messianic expectations onto education which, since the seventeenth century, was supposed to ensure perfection in this world.

‘Reform,’ therefore, was never just pragmatic; it was, at the same time, a utopia that did not lose track of the salvation concept and could also understand education as a power and cause of the radical renewal. The success of this was considered to be all the better the more education could appear to be methodically mastered—a concept that was promoted by the ‘inwardness’ of belief within the European Reformation. The ‘inner belief’ should be granted by new education, and this required means of influence. The Baroque programs convinced by way of a mixture of ‘whole-

ness’ and ‘method.’ Similarly, sensualistic psychology in the eighteenth century was understood as a strengthening of the effectiveness of education, and pedagogical doctrines were developed with the promise of methodical innovation. At the same time a literary image of the child was created between Rousseau and the Romantic era which particularly excluded technical expectations. The reform movements of the nineteenth and twentieth centuries developed in this field of tension of ‘natural education’ and ‘method.’

2. Reform Movements in the Nineteenth Century up to World War I

‘Education nouvelle,’ ‘progressive education,’ ‘*Reformpädagogik*’ or ‘*nuova educazione*’ are subsequent historiographic descriptions of widely divergent reform groups and reform concepts which, from the final third of the nineteenth century, opposed the foreseeable damage and weaknesses of the developing educational system. The ‘grammar of schooling’ (Tyack and Cuban 1995), i.e., the institutional form of the modern school, developed during the nineteenth century as a single comparable system in the individual national states. Compulsory schooling was created everywhere, teachers were professionally trained for undertaking tasks of the state, and schools developed specific institutional procedures and forms such as the grading of pupils in age groups, the dominance of subjects, largely frontal forms of lessons, the assessment of pupils’ performances using grades or marks, and so on.

The weaknesses of this system were the initial theme of the reform movements, which already had international links by 1914, but in a practical sense were largely geared towards their respective national systems. Influential authors of the nineteenth century were guided by parameters laid down by Jean-Jacques Rousseau or J. H. Pestalozzi. Rousseau was considered a pioneer of natural education, while Pestalozzi was an authority on education according to moral ideals; both concepts were employed more and more against the institutional development of the school. Friedrich Fröbel’s Kindergarten was of particular importance to the development of the reform movements. Central motives of the reform movements at the end of the nineteenth century, such as the focus on children, the playful manner of learning, or active methods of teaching, were disseminated in the kindergarten media, even if the practice did not always comply with the theory.

Compared with the state school development, these attempts were marginal during the nineteenth century, albeit much discussed and widely published. Significant school-reform movements were only established at the end of the nineteenth century, in a manner which covered three issues. In England and continental

Europe private alternative schools in the area of higher education ('*Landerziehungsheime*') were established which replaced or supplemented the former private school institutions. In the area of elementary school education, reform initiatives were established, above all, where social democracy gained an influence. And third, life reform movements were linked in a very different manner to the school initiatives. One of them was the Theosophical Society, which can be seen as the most influential international individual grouping of educational reform at the end of nineteenth century. In Germany it resulted in the establishment of Rudolf Steiner's Anthroposophical movement (founded in 1912). The establishment of the 'Waldorf School' (1919) in Stuttgart was the start of the largest private school reform movement to date. The new '*écoles nouvelles*,' which were established in England, France, Switzerland, Germany, and various other nations, represented the successful utilization of a pedagogical niche. In 1910 some 100 schools were registered; these operated on the basis of full-day boarding schools as 'educational communities' with a particular curriculum. These schools created a demand because they were able to respond to the dissatisfaction, above all of middle-class parents, with the rigid forms and outdated contents of the grammar schools. Furthermore, country boarding schools often provided the only opportunity to actually achieve university entrance qualifications.

School establishments on the basis of political and social change have been undertaken time and time again since the Owenite Movements in England and the USA. In 1825 the first socialistic school community was established in New Harmony, Indiana. However, most of these did not enjoy lasting success. Only a few alternatives outside the nineteenth-century association of home, school, and church were successful. The pedagogical reform movements were not only grounded in spiritual and/or political world views. Theories of child psychology were to permanently strengthen the intuitions of 'new education': the physiological evidence of the independent development of the senses and feelings, the description of the development of the child according to natural 'phases' or 'stages,' and the recording of the milieu and behavior of children in research facilities.

Together with the exemplary models of the school reform, this knowledge was authoritative for the development of teacher training. The focus of attention of the reform movement in the USA was Columbia University's Teachers College, established in 1897. Its Kindergarten and Elementary School became the experimental focus of child-centered education in the 1920s (Rugg and Shumaker 1928, Ravitch 1986). However, the Teachers College was, above all, a research center. Thus, it was not only activism, but psychological and educational research that was responsible for the success of 'new education.' In 1912 the Institut Jean-Jacques Rousseau was established in

Geneva. The year 1915 saw the establishment in Berlin of the Zentralinstitut für Erziehung und Unterricht, while in 1920 Ovide Decroly established his institute of psychological research, which had previously been private, at the University of Brussels. In 1922 the London Institute of Education was set up on the lines of pedagogical reform.

These developments were favored by the cultural and social *cesura* of World War I. After 1918, political educational reforms were called for in all continental European societies, which were aimed at reacting to the devastating effects of the war. In England a radical education sector came into being; it was, however, intended to, or was forced to, operate outside the system of public education. In the USA, April 1919 saw the establishment of the Progressive Education Association (PEA), which was aimed at changing nothing less than the entire American school system (Cremin 1964, p. 241). Its public influence was considerable, also because after 1930 the academic world was opened up for 'new education' mostly via Teachers College (Cremin 1964, p. 250). The French *éducation nouvelle* gained considerable influence at the same time in the entire francophone educational world, to the extent that at the end of the 1930s the term '*expansion mondiale*' was being applied to the new education.

3. *Pedagogical Reform Between the Wars*

Three developments are of considerable importance to the period between World War I and World War II: the establishment of canonical convictions of what 'new education' is, including the appertaining major figures of eminent reformers, the development of international structures, and the very divergent politicization of the 'new education.' The core of the doctrines was child-centeredness. Education should follow the spiritual, physical, and mental growth of the child. The educational institutions must adapt their actions in line with the natural development. The mode of education dispenses, as far as is possible, with external determination, and thus dispenses with authority.

The reception of Freud's psychoanalysis and the beginnings of child therapy were of great public importance, alongside the liberal concepts of sexual education, which were discussed and practiced in all European major cities up to 1933. It was envisaged that there should be great liberty in early childhood sexuality, and considerable credit was given to Freud for this discovery. The pedagogical reception of Freud, however, is contradictory and selective—not only because of Freud's late theory of drive and aggression but also because its related cultural criticism does not fit in with the optimistic picture of a child developing in accordance with its good nature. Most reformers subscribed to the picture of the good and independent

child that cannot become neurotic or destructive unless pedagogical authority causes it to be so. This picture was simultaneously that of a gender-neutral, culturally independent and socially free child which, precisely as Rousseau had stipulated, exists for itself and needs only to be protected from damage.

The Montessori pedagogy, which became influential in England, the Netherlands, Germany and Italy, was probably the largest international education movement of the 1920s and 1930s. It saw the establishment, in each case, of independent, usually female sponsor groups, with their own communication organs and an international network. The case in Italy is particularly interesting from a political point of view, because Montessori here was not considered the actual pioneer but the theorist of the '*nouva educazione*.' Montessori cooperated with the Fascist regime between 1923 and 1933 to promote her method. 'New' education's focus on the child was the subject of a dispute between Dewey and the Progressive Education Association; they were, however, never able to dissolve the dualisms 'child' and 'curriculum' or 'child' and 'society.'

The international meetings of the New Education Fellowship, which began in 1921 in Calais (topic of conference: 'The Creative Self-expression of the Child') and which ended in 1941 in Ann Arbor (topic of conference: 'Education in a World of Nations') demonstrate the scope of tension between pedagogical reformers' concentration on the child, the creative powers within the child, and the drama of world politics. It is not by chance, therefore, that the pedagogical reform appeared to be torn between the fronts of the Cold War. The Progressive Education Association was dissolved 1955 without much ado under the impression of massive criticism of the liberal and child-centered education which was held responsible for the backwardness of the American education system.

4. *Radical Years*

In 1960 Paul Goodman recollected, with reference to Bertrand Russell and Alexander Neill, the courageous 1920s and the 'revolutionary' attempts of the progressive education movement (Goodman 1960, Sect. IV/6). These attempts had, in fact, failed (Goodman 1960, Sect. IV/7), but they had not been in vain, because the education of the 'beat generation' had to link up with the movement. In the same year, 1960, the New York publisher Harold Hart put out a compilation of texts by Alexander Neill from the 1920s and 1930s under the title *Summerhill: A Radical Approach to Child Rearing* which, by 1970, had reached a circulation of more than two million copies in the USA alone.

Neill, Holt, and Goodman were initially underground authors, at least in America. The international student movement of the 1960s ensured that the

concepts of the 1920s could be once again understood as for avant-garde society's innovations. John Holt's *How Children Learn* (1970) was a strong confirmation of the child-centered pedagogy without these themes being particularly historicized. They were rewritten and adopted for a new generation. Goodman's 'beat generation,' which is actually a negative description that fits with the deficit formula of educational reform, could be related to an experience of emancipation which applied, in particular, to the educational institutions. The cultural revolution was directed against the pedagogical authorities, while projects focussing on self-experience were promoted. Again, formal school education came under attack; the 'new education' (Postman and Weingartner 1969, chapter 8) was aimed at binding school knowledge to subjective meaning (Postman and Weingartner 1969, chapters 5 and 6) without further following a state curriculum. Compulsory education was called into question as 'compulsory mis-education' (Goodman 1964).

The radical approach of the educational reformers in the 1960s was not new. What is new in the USA is the link between progressive education and society reform movements which extend beyond the New Deal positions. This includes the civil rights movement, the women's movement and minorities, as well as third world movements. Paulo Freire's *Pedagogy of the Oppressed* (1970) is perceived by the leftwing American pedagogy as a change in the traditional European-centered reform discourse. The same applies to Ivan Illich's radical criticism of schooling, which goes back to ideas of the Centro Intercultural de Documentacion in Cuernavaca, Mexico, established in 1964. Subsequent to this criticism, the matter in question was no longer school reform, or applying the avant-garde position in the life reforms movements or cultural criticism; the focus now was on education and training.

The 'new education' was understood on one hand as a political strategy of liberation in view of third world problems. On the other hand it was seen as a withdrawal of all demands which were not compatible with the ideal of human liberty. Therefore, it was not by chance that John Holt's *Escape from Childhood* (1975) brought the radical years to an end. Even free and alternative schools such as Summerhill, Holt said, can fail, and, in fact, in greater numbers the more they have tied the happiness of children to their masts (Holt 1975, chapter 14). The problem can only be solved if the pedagogic differentiation between 'adults' and 'children' disappears, and children are granted the same rights as adults (Holt 1975, chapters 15 and 16).

In Europe and England there were comparable radicalizations which allowed for the fundamental negation of education from the linking of education with emancipation in little more than 10 years. This 'anti-pedagogy' is often justified with theories of depth psychology which also demonstrate how strong the effect of educational reform was in the 1920s; only

what was previously understood as a radical start of the 'new education' is now seen as a negative development. The brief recurrent link between movements of societal reform and 'new education' could not be renewed, among other reasons because it became evident that the 'new education' had been merely a historical project that did not allow for general applications such as change of society.

5. Conclusion

The real history of education of the twentieth century has confirmed rather than changed the national systems in place, irrespective of the political catastrophes and the affiliated radical breaks in culture and society. Evidently schools are robust systems which renew themselves from within and in this respect adapt those aspects of progressive education that are acceptable. These innovations never put the entire system at risk. During the 1990s this structural conservatism produced entirely different reform movements which linked up neoliberal economic theories with the old positions of freedom of learning or self-determination. Looked at from the point of view of privatization, efficiency, and commercialization (Chubb and Moe 1990), the criticism of school bureaucracy of the nineteenth century has reappeared, along the renewal of the theory of 'death of the school,' through the revolution of the interactive learning media (Perelman 1993). The critique of schooling substantiates the home schooling movement, accompanied with an internet service for freedom from schooling.

The new movements founded in the 1990s are not turning their backs on reform pedagogical motives. Criticism is now leveled at ineffective and inactive institutions whose organizational form and sponsorship should be radically changed, but there is little consensus concerning the direction in which this change should proceed. The motives are based on political change as much as on maintaining family values, and they have liberal as well as community justifications on which agreement is ultimately unlikely to be reached. As ever, the discourse on how to reform education is ongoing.

J. Oelkers

Peer Review and Quality Control

Peer review is a mechanism for quality control in science, including the assessment of proposed projects and also of completed work. Its roots go back to the emerging science of seventeenth century, when novelty in natural knowledge became distinguished from technical invention and the ideals of reproducibility and publicity became established. Peer review was acknowledged by the mid-twentieth century as the unquestioned norm in 'academic science.' By then it was assumed that quality was unproblematic, owing to some special ethical disposition of scientists and their methods. With subsequent transformations in the social practice and context of science, which now extends into technology and policy, corresponding changes in quality assurance are needed. The crucial requirement is for a more encompassing community of those evaluating the products and processes of science (see, e.g., Stampa 1997).

In most other spheres of institutional activity, the formalization of quality assurance has become the norm, as for example through the wide-ranging standard-setting procedures of the International Standards Organization (ISO). In academic science, however, along with cultural pursuits like the arts, the methods are still largely informal. Science has been almost unique in having self-assessment performed by practitioners rather than by external 'critics.' To what

extent and in what ways this must change to keep pace with science's expanding role in public life has become an urgent question in the governance of science.

The assurance of quality is not a straightforward task. This has been known since the time of the Romans, as indicated by the Latin motto *quis custodiet ipsos custodes?* (Who will guard the guardians themselves?). This motto implies an indefinite iteration. It is a reminder that, however, routine may be the tasks of quality control, full quality assurance demands yet higher levels of supervision at which informality and explicit value judgments are necessary.

As long as science remained mainly academic, problems of quality were assumed to be resolved by the very nature of the scientific endeavor. The informal systems of checking by peers seemed a rational response to the problem, rather than a culturally contingent mechanism characteristic of a particular epoch. Scientific facts were believed to be discovered by an infallible method, and scientists themselves were viewed as being endowed with certain superior moral qualities that protected them and their work from ordinary human failure or error. This self-correcting property of science could be explained in sociological terms, as in the 'four norms' of scientific practice expounded by Robert K. Merton in 1942 (Merton 1973), or philosophically, as in the committed attempts at self-refutation supposed by Karl Popper to be normal scientific practice (Popper 1959).

With the onset of the industrialization of science after World War II, the self-conscious study of science as a social activity, including the methods of quality assurance, became inevitable. Growth in size, capital investment, scale, and social differentiation within science created divisions between managers and research workers, as well as between researchers and teachers in universities. A *Gemeinschaft* (community) of scholars could no longer realistically be assumed. The earliest disciplined analyses of the quality of production in science were quantitative. Derek J. de Solla Price, who devised some measures of quality and provided analyses of its distribution, did the pioneering work. He noticed that at the leading British science reference library only a minority of journals was ever requested. The contents of the others could be inferred to have no interest, and hence to be of very low scientific quality (Price 1963). This phenomenon is a reminder that 'quality' is a relational attribute. 'Fitness for purpose' depends on whose purposes are dominant; not always perhaps those of a community devoted to the advancement of learning, but possibly only of those scientists working under constraints of 'publish or perish.'

Price's studies were continued in two directions. At the Institute for Scientific Information, Eugene Garfield produced more searching and sophisticated measures of quality, using citations rather than mere number of publications. Such attempts at quantification were bound to become controversial (Brooks

1982, Garfield 1970, 1972). It was impossible to avoid bias in the selection of the relatively small set of journals used for citations; those in conventional mainstream English-language research science were inevitably privileged at the expense of all others. Further, when quantitative measures of citations came to be used as indicators of academic merit, manipulative practices, including reciprocal citations, inevitably developed. The deep problems of a quantitative proxy for quality suddenly became acute.

In a more reflective vein, Jerome R. Ravetz applied the *quis custodiet* principle to analyze the vulnerability of the quality assurance system in science. He observed that the processes of peer review are conducted largely informally and (unlike research) are not themselves normally submitted to open scrutiny and review. They require a different sort of competence, which is not part of the formal training of scientists; and they are also more open to a variety of abuses, ranging from bias to plagiarism. One can understand the phenomena of low quality, both in scientific research and in technological development in these terms. Thus, while denying that the practice of science automatically produces a higher morality, Ravetz agrees that moral standards are necessary for the successful practice of science. On this basis he stresses the importance of morale and morality (and ultimately idealism and leadership) in science (Ravetz 1996).

This analysis provides a background for the increasing interest in 'trust' as an essential element of practice in science, in society, and in their interactions. The broader society has provided resources to the esoteric activities of science because it trusts the scientific community to make good use of them. There has always been an undercurrent of distrust, based on evidence either of pointless research or of malign applications. Once science became deeply involved in technology and related policy problems that crucially affect public health and welfare, the traditional relations of trust could no longer be assumed. It appeared to be necessary for the principles and practices of accountability to be extended from the institutions of political governance (as, e.g., representative democracy) to those institutions, which govern science and its applications.

Quality control in research science has become more difficult as the relatively inflexible technical requirements of the traditional printing process have been relaxed. There is no longer a well-defined 'gateway' to publication through the institutions that control reproduction of, and hence access to documents. First through inexpensive photocopying and now through the Internet, it has become easy for anyone to distribute scientific wares to an unrestricted audience. In addition, the presence of the global media tends to bypass the traditional processes of evaluation, which were conducted personally among colleagues. Isolated scientific results can become media events (Close 1991). All those with an interest in the report, such as

consumers, politicians, regulators, and the stock markets, become potential stakeholders in the evaluation of the result. Thus, science arguably becomes accountable to a drastically extended peer community in the quality-assurance process. The criteria of quality applied by these heterogeneous actors need not be identical to those of 'public knowledge' generated within tightly knit scientific networks.

These developments may be judged in different ways. While they may seriously disrupt the procedures of quality assurance in normal science, they can also bring needed public scrutiny to bear on controversies and scandals. The demystification of scientific practice both enables such events to become news, and is fostered by their being exposed. Top scientists become like celebrities—needing the media for advertising themselves yet simultaneously hating it for its unwanted intrusions. The 'Baltimore affair,' centering on the US Nobel laureate David Baltimore's laboratory at MIT, is perhaps the most notorious case in which a dispute about scientific misconduct was blown up into a lengthy, visible, political saga that damaged all the individuals and institutions involved (Kevles 1998). The episode was symptomatic of an increasingly recognized problem of 'deviance' in science, which carries the unspoken danger that, without timely correctives, misconduct might become the norm.

All these developments affect the maintenance of trust, which is necessary for ordinary scientific practice and even more for quality assurance. As in other professional domains, the normal tendency in science has been for misconduct to be covered up by the responsible institution (not necessarily by the community of scientists). In such situations, ultimate exposure does even more damage and further erodes the basis for mutual trust. Attempts to circumvent the need for trust by increasing bureaucratic surveillance are likely to be counterproductive in their own way, by erecting impediments to free inquiry and communication among colleagues.

The relations between social science and natural science have also been transformed during the last decades, with implications for quality control. Starting with the acceptance of natural science as the ideal of knowledge, essentially independent of social forces, there has been a gradual but accelerating shift toward recognizing all sciences as incorporating social constraints and biases. An early critical interaction was in connection with the astronomical community's management of the eccentric Velikovsky (de Grazia 1966). Later, the social science community embraced Thomas Kuhn's disenchanting picture of 'normal' science (Kuhn 1970). Finally, post-Feyerabend studies of science re-examined the whole institution of scientific inquiry without presupposing any privileged status in relation to either virtue or natural knowledge (Bloor 1991, Bloor et al. 1995, Collins and Pinch 1993, Fuller 1993).

When natural scientists, led by physicists, eventually

confronted the emerging socialized picture of their discipline, the reaction was so strident that 'science wars' became an appropriate label (Gross et al. 1997, Nelkin 1996, Ross 1996). Sociologists of science and post modernists were indiscriminately blamed for all the ills of science, including decline of public trust, budget cuts, resurgent Creationism, and even poor teaching of science. A physicist whose hoax article (Sokal 1996) was accepted by a leading cultural studies journal, *Social Text*, helped to crystallize the attack (Bricmont and Sokal 1998). The implication was that the critics of science had no real quality control of their productions. The science warriors' assumption was that within real science, such problems are prevented from occurring because of the verifiable empirical content of scientific research. In the ensuing debate, there was little mention of the ease of publication of erroneous or vacuous research in the standard scientific literature. Historical episodes, like Millikan's manipulation of his oil-drop results in the course of a controversy on the charge of the electron, were discounted as mere embarrassments (Segerstale 1995).

It has been presupposed thus far that 'science' refers primarily to traditional basic research. But among contemporary forms of scientific practice, curiosity-driven research with no regard for applications has been increasingly marginalized. A diversification has occurred, so that quality assurance must also be considered in such areas as mission-oriented and issue-driven research, forensic science (Foster and Huber 1997, Jasanoff 1995), and the provision of scientific advice for policy (Jasanoff 1990, Salter 1988). In addition, the products themselves and the media through which they are diffused increasingly are diversified. For example, patents are now a common outcome of a research process, and this form of intellectual property is radically different from traditional published papers (Myers 1995). Also, results are reported in unpublished consultancy advice and unpublished 'gray literature' or kept confidential within institutions or even totally sealed under 'lawyer-client confidentiality' and legal settlement agreements. With traditional peer review as the norm, the challenges of quality assurance for these new products and processes are nearly unrecognizable. A genre of critical literature has developed, with some authors directing anger at the new contexts of scientific production (Huber 1991), and others more clearly appreciating the problems they present (Crossen 1994, Jasanoff 1990, 1995).

A parallel diversification has occurred in the types of knowledge production that are accepted as legitimate. The democratization of knowledge now extends beyond the juries who assess the quality of technical evidence in courts (Jasanoff 1998) to include those who master previously esoteric aspects of their predicament (e.g., illness, contamination, pollution, oppression, discrimination, exploitation) through special-interest groups or the Internet. In addition,

claims of specialized or local knowledge are present in even more diverse contexts, as among indigenous peoples, and in systems of complementary or 'traditional' medicine. These claims are commanding increasing commercial and political support among various publics, as well as gaining explicit recognition in numerous international treaty regimes. As a result, a new philosophy of knowledge appears to be emerging, based on a new disciplined awareness of complexity, in which a plurality of legitimate perspectives is taken for granted (Funtowicz and Ravetz 1991). Modern science, with its characteristic methodology and social location, is part of this enriched whole, but not coextensive with it. The criteria and tasks of quality assurance must explicitly involve additional values and interests, incorporating even the ontological commitments of groups other than scientists. This new configuration has been termed postnormal science.

Quality assurance can, thus, be seen as a core commitment of postnormal science, replacing 'truth' as science's ultimate regulative principle (Funtowicz and Ravetz 1992). Defined in terms of uncertainties and decision-stakes, quality assurance encompasses 'public interest,' 'citizen,' and 'vernacular' sciences. In a period of domination by globalized corporate science (Gibbons et al. 1994), this effort to make scientists accountable to interested groups presents a coherent conceptual alternative for the survival of the 'public knowledge' tradition of science. Collegial peer review is thereby transformed into review by an 'extended peer community.' This new form of quality assurance will be given its formal structure and routines by those heterogeneous actors who put it into practice.

People in Organizations

Organizational researchers study how individuals and organizations interact with their environment to accomplish both individual and collective goals. People are able to accomplish goals in organizations that they would be unable to accomplish alone, and they spend large portions of their lives interacting in organizational contexts. The complexities that emerge from bringing people together in organizational settings, therefore, provide a fascinating lens into the human experience. Organizational research brings together psychology, sociology, economics, and anthropology to examine both individual-level processes at work, as well as the organizational-level processes that dictate how firms relate to each other and their environment.

Reflecting this focus on both individuals and organizations, the field is split between ‘macro’ organizational behavior, drawing upon organizational sociology, and ‘micro’ organizational behavior, drawing upon social, personality, and industrial-organizational psychology. Macro-organizational behavior is concerned with the various strategies organizations use to adjust to their environment, such as the development of networks between firms. In contrast, micro-organizational behavior is concerned with the way personal characteristics combine with contextual features such as task, group, and organizational characteristics to predict work outcomes. Though the strength and uniqueness of organizational behavior rests on the equal emphasis of both individual and organizational processes and the utilization of a variety of research methods that cross disparate levels of analysis, our focus in this article is on micro-theory and research. Excellent reviews of macro-organizational theory can be found elsewhere in this collection (see *Organization: Overview*; *Administration in Organizations*; *Organizational Control*; *Organizational Culture*; *Organizations: Authority and Power*) and in Carroll and Hannan (2000) and Scott (1998).

1. Micro-theory: Person–Situation Interactions

Micro-organizational behavior examines both personal and situational characteristics and, as in the field of psychology, researchers debate the relative utility of each in explaining behavior. Some have emphasized the stability of attitudes and behaviors over time. For example, a person’s satisfaction with his or her job remains relatively stable over years and even decades (Staw and Ross 1985). From this perspective, individual characteristics are the best predictors of behavior since they derive from personal dispositions

that remain stable over time and across situations. Others have criticized this view and posited that organizations should be conceptualized as ‘strong’ situations that are powerful enough to shape individual behavior (e.g., Davis-Blake and Pfeffer 1989). In strong situations individual differences are unlikely to be expressed. Instead, people learn appropriate attitudes and behaviors from their co-workers, established norms, and organizational practices and procedures; these social influence processes are presumed to predict individual behavior better than are personal characteristics.

Researchers have typically considered personal and situational factors in isolation from one another, but a complete understanding of organizational behavior requires their simultaneous consideration. An interactional approach is more complex than a mere additive melding of personal and situational characteristics because it attempts to represent both personal and situational factors and their reciprocal influence.

Interactions between personal and situational characteristics may take at least four forms. First, as specified above, some situations are stronger than others, leading to different levels of behavioral uniformity. Second, work situations do not affect everyone in the same way; some people’s behavior is more consistent across varying situations. Third, certain people, such as those exhibiting ‘charismatic’ leadership, can influence situations more than others. Finally, people do not select into situations randomly, but rather, into situations in which they think their attitudes and behaviors will be appreciated. Developing a complete theory of behavior in organizations, then, requires moving from considering personal and situational factors in isolation to considering the complexity and diversity of possible person–situation interactions and their effects on work outcomes. We illustrate this by identifying the types of person–situation interactions that are relevant to a set of vibrant research domains within organizational behavior: organizational culture, demography, leadership, and creativity.

2. Organizational Culture: Selection, Socialization, and Person–Culture Fit

Research on organizational culture has demonstrated that norms and values can shape individual behavior. Recent research has also demonstrated that behavior can be predicted by understanding how personal characteristics interact with cultural context. Below we discuss the four types of person–situation interactions as they relate to organizational culture.

2.1 Organizational Culture as Strong Situation

Though researchers agree that organizational culture is meaningful and important, they do not agree about how to define and measure it. Organizational culture

research typically draws upon theories in anthropology or cross-cultural psychology and uses ethnographic or quantitative methodologies. Some researchers have emphasized shared values and meaning (O'Reilly et al. 1991) while others have emphasized the ambiguity of cultural values and the existence of subcultures (Martin 1992). Most agree that the existence of different perceptions among members does not preclude the existence of shared assumptions. Organizational culture can be understood as a system of shared values and norms that define what is important and how organizational members ought to feel and behave. Through members' clarity about organizational objectives and their willingness to work toward these objectives, culture influences the attainment of valued organizational goals by enhancing an organization's ability to execute its strategy. This conceptualization focuses on two primary aspects of culture: first, the extent to which agreement and intensity exist about values and norms (culture strength), and, second, the extent to which these norms and values differ across settings in important ways (culture content).

Culture content refers to shared values and norms that define desirable behavior in the organization. For example, some cultures may stress the value of being a 'team player' while others may emphasize independence. For a culture to be strong, members must agree about which values are important and be willing to enforce them strenuously. Members of an organization may agree that they value, for example, being cooperative, but unless unequivocal and salient consequences result from compliance (e.g., cooperating with co-workers) and non-compliance (e.g., competing with or undercutting co-workers), the culture cannot be characterized as strong. A strong culture is characterized by social control in that members both agree about and are willing to enforce values and norms, even if such enforcement violates hierarchical lines of authority. Further, greater behavioral homogeneity among members, for better or worse, should be observed in stronger organizational cultures.

Cultural values are conveyed to members through the socialization processes that new recruits experience when they enter an organization. Though socialization often takes the form of training and contributes to increased task knowledge, information about the norms of the organization is also transmitted through training and other types of socialization (Morrison 1993). Interestingly, such normative information appears to be transmitted very early in new recruits' membership since cultural fit changes little after members' first year (e.g., Rynes and Gerhart 1990).

2.2 Behavioral Consistency Across Various Organizational Cultures

Although culture influences members' behavior, they are not merely passive recipients of social control.

Individual characteristics may interact with the organization's culture to predict important behavioral and work outcomes. Research on person-organization fit, defined broadly as the compatibility between people and the organizations for which they work (Kristof 1996) has focused primarily on congruence between patterns of organizational values and patterns of individual values. New employees whose values more closely match those of the organization view it as more attractive, are more likely to join when made an offer, are able to adjust to it more rapidly, perform better, are more satisfied, and remain with it longer (e.g., Chatman 1991).

But, just as organizational cultures may differentially affect behavior, people may also differ in the extent to which their behavior is shaped by an organization's culture. For instance, compared to individualists, cooperative people were more responsive to the individualistic or collectivistic norms characterizing their organization's culture, and exhibited greater behavioral adaptation to each across the two types of organizational cultures (Chatman and Barsade 1995). Thus, congruence models, which presume an additive equivalence of person and situation factors and assume that greater congruence is always better, cannot fully explain behavior in organizations. Instead, a focus on mismatches between person and organization characteristics that challenge people to either act in accordance with the culture and thereby contradict enduring personal tendencies, or vice versa, might generate insight into such interactions.

Future research might focus on the set of characteristics, such as cooperation, self-monitoring, and self-esteem, that contribute to people's flexibility across situations. Identifying such characteristics could improve predictions of the behavioral expression of person characteristics both across time and across situations, and in particular, the extent to which an organization's culture and processes will influence member behavior. Research might investigate other organizationally relevant matches and mismatches to understand how different situations influence person-situation interactions. For example, examining mismatches between honest people and dishonest organizations may help to identify if and when good people 'turn bad.'

2.3 Individuals' Influence Over Organizational Culture

Founders and senior executives, who have legitimacy and authority, may be the most influential individuals in an organization. The person who creates the organization has significant impact on the strategies that the group develops to survive, and these are often preserved in the organization's values, practices, and promotion patterns well past the individuals' actual presence. Ironically, newcomers, who are at the other end of the spectrum in terms of authority and

legitimacy from founders, may also exert a great deal of influence on culture. This influence may be indirect; research has shown that the process of recruiting new members, including emphasizing an organization's attractions, strengthens current members' connection to their organization (Sutton and Louis 1987), and can exert mutual learning of the organizational culture (March 1991). An organization's culture may also be transformed by the entrance and exit of its members. Thus, the strength of an organization's culture may depend on the individual mobility of its members. Using simulation methods, organizations' length of service distributions have been examined as indicators of the extent to which members have been socialized into the culture's norms and values. This research has shown that variations in service distributions are positively associated with heterogeneity in organizational culture due to three distinct cultural processes: socialization, group cohesiveness, and common historical experiences (Carroll and Harrison 1998).

2.4 Situation Selection Based on Organizational Culture

Schneider (1987) developed the Attraction–Selection–Attrition (ASA) model, which posits that the key factor influencing the relationship between people and organizations is the fit between individual personality and the modal personality represented in the organization. People are differentially attracted to organizations on the basis of the anticipated fit between their own characteristics, such as personality traits, and organizational characteristics, such as culture (e.g., Cable and Judge 1997). Job seekers take an active role in the recruitment process and are attracted to careers and organizations reflecting their personal values and interests. Further, organizations have developed formal and informal strategies to identify and select recruits who will be compatible with their goals and working environment, elements that are strongly influenced by an organization's cultural values. For instance, rather than focusing on job-related criteria, selection appears to be based on such socially based criteria as 'personal chemistry,' and fit with the organization's values.

3. Organizational Demography

People may differ from each other in many ways that are both observable and unobservable. Members' observable demographic characteristics constitute a context for every other individual in the organization. For instance, a lone newcomer in an organization of established members may have a very different experience than a newcomer entering an organization characterized by members with varying tenure. Given

the dramatic changes in US labor force demography over the past decade, relational demography, or the distribution of demographic characteristics within organizations, has become an active area of research.

Research on organizational demography improves upon past research on employee turnover. Turnover typically indicates a discrete departure event while demography focuses on length of service and rate of departure by taking into account the distribution of people by the length of time they have spent in the organization. This distribution can be influenced by a host of factors including personnel policies, technology, and the degree of unionization in the workforce (Pfeffer 1983). Most research on observable differences has examined the effect of demographic heterogeneity versus homogeneity on performance and has yielded mixed results (see Williams and O'Reilly 1998 for a comprehensive review). Some studies have demonstrated the positive effects of demographic heterogeneity for increasing the number of novel perspectives that can be used to solve difficult problems, increasing an organization's network of contacts, and facilitating organizational change. However, demographic heterogeneity may also lead to communication problems, less social integration in workgroups and greater turnover (e.g., Tsui et al. 1992). Demographic distribution among members across various attributes is an important situational factor that deserves further research since it can influence behavior differently depending on an individual's own demographic profile.

3.1 Behavioral Consistency Across Demographically Heterogeneous Workgroups

Research suggests that an organization's culture may influence the relationship between demographic diversity and work outcomes. For example, the purported benefits of a demographically diverse workforce are more likely to emerge in collectivistic organizations that make organizational membership more salient than membership in a demographic category (Chatman et al. 1998). An organization's culture may dictate the extent to which members view certain demographic characteristics as valuable and others as associated with lower status within an organization's informal social system (Spataro 2000). Furthermore, each attribute, such as tenure, race, or sex heterogeneity within a group, may differentially influence individual behavior and the combinations of various attributes can result in 'fault lines' which become stronger as more attributes align themselves in the same way (Lau and Murnighan 1998).

One explanation for the lack of clarity about the benefits and detriments of diversity is that researchers have neglected to consider key mediating processes between demographic composition and performance.

As shown in one recent study, heterogeneous groups initially created norms fostering independence rather than cooperation among members, but cooperative norms subsequently mediated the relationship between group demographics and performance (Chatman and Flynn, 2001). Similarly, a group's level of conflict influenced the impact of demographic heterogeneity on performance (Jehn et al. 1999).

4. Leadership

4.1 *Some Individuals Can Effect Change More Than Others*

Early leadership research focused on the physiological and psychological traits thought to be associated with exceptional leaders. These 'great man' theories of leadership examined the effects of personal characteristics such as height, physical appearance, and intelligence on leaders' emergence and effectiveness. This stream of research has its counterpart in more current studies examining the effects of self-confidence, extraversion, and energy level (e.g., House 1988). The aim of this approach has been to identify a leadership personality. However, it leaves many crucial questions unanswered, such as whether certain personal characteristics become more important than others depending on the organizational context, and why, regardless of formal authority, followers perceive some people as leaders and not others.

Contingency theories of leadership were advanced to explain how certain personal characteristics made a leader effective in certain situations (e.g., House and Baetz 1979). For example, leaders who initiated structure raised the productivity and satisfaction of a group working on a boring or simple task but lowered the productivity and satisfaction of a group working on a complex task, while a considerate leader raised the satisfaction and productivity of a group engaged in a boring task but had little effect on a group engaged in a task they found intrinsically interesting. Additionally, research showed that allowing members to participate in decision making increased commitment but depended on the amount of trust the leader had in his or her subordinates as well as the urgency of task completion (Vroom and Jago 1978). Thus, contingency theories of leadership were more comprehensive than trait theories; however, they still did not account for the interactive effects of leader characteristics and their situational contexts.

Recent research has focused on charismatic and transformational leadership, demonstrating that some individuals influence situations more than others. This research takes an interactional approach by conceptualizing leadership as a personal relationship between the leader and his or her followers. A leader must have certain interpersonal skills in order to inspire followers to set aside their goals and to pursue a common vision. Charismatic leaders are thought to

have the ability to change their circumstances by increasing followers' motivation and commitment and, sometimes, to change the direction of the entire organization (e.g., Meindl et al. 1985). However, a leader is only charismatic if followers recognize him or her as such; followers must identify with the vision articulated by the leader. In one particularly exhaustive laboratory study of charismatic leadership (Howell and Frost 1989), confederates were trained to display qualities of a charismatic leader, such as projecting a dominant presence, articulating a large overarching goal, and displaying extreme confidence in followers' ability to accomplish this goal. In addition, norms were created in each group for either high or low productivity. In contrast to participants working under a considerate or structuring leader, participants working under the charismatic leader displayed higher task performance regardless of the group productivity norm. This finding suggests that leaders mold their styles in response to the situation. Moreover, some leaders are capable of changing the situation itself by changing followers' perceptions and motivation.

4.2 *Leadership as a Function of the Strength of the Situation*

Some researchers have been skeptical of a leader's ability to change situations, and have suggested that leadership is far more situationally determined than might have been assumed. The attributional theory of leadership suggests that because people tend to associate certain behaviors with those of a leader, leadership qualities will be attributed to a person displaying these behaviors (Calder 1977). Various biases emerge from this attribution, however. For instance, individuals tend to overestimate the amount of control a leader has over events that are, in fact, random or uncontrollable (Pfeffer 1977). Furthermore, a leader will be given more credit when situations are unfavorable (Meindl et al. 1985). Individuals' lay conceptions of leadership can be used or misused for the purposes of organizational impression management (Ginzel et al. 1993). In sum, leadership research has focused more on contexts and followers rather than on the characteristics of a focal leader. Future research might examine whether leaders reflect the personal characteristics of their followers or complement their weaknesses, if some followers have a greater psychological need for leadership than others, and the various substitutes for leadership, or how people can be compelled to lead themselves.

5. Creativity and Innovation

Research on creativity, like leadership, has moved from emphasizing traits, to considering the organizational context as well as the interaction between the

two. Creativity is generally viewed as distinct from innovation. Creativity occurs at the individual level, and refers to the generation of ideas that are both novel and useful. Innovation refers to the process of implementing these ideas at the organizational level.

5.1 *Some People Are More Creative Across Situations Than Others*

Early creativity research focused on the personality traits associated with individuals who had made creative contributions in their respective fields. People who have a wide variety of interests, are attracted to complex tasks, tolerant of ambiguity, and self-confident perform more creatively (e.g., Barron and Harrington 1981). However, trait research ignores how organizational contexts influence people's ability to perform creatively.

5.2 *Some Situations Foster More Creativity Than Others*

The degree to which one's job encourages intrinsic versus extrinsic motivation affects one's creative performance. Early studies suggested that when people worked on tasks that they found intrinsically interesting, adding an extrinsic reward lowered their interest in performing the task for its own sake (Deci 1971). More recent studies in organizational settings showed that individuals were most creative when they were intrinsically motivated. This intrinsic interest led them to stay focused, persist longer to complete difficult tasks, to 'play' with ideas, and suggest novel solutions (Amabile 1988). This suggests that the situational factors that are associated with decreases in intrinsic motivation, such as a controlling supervisory style, and an emphasis on external rewards, may indirectly diminish people's creative potential.

Organizational culture also influences creativity and innovation. Organizations that have mechanisms to express confidence in members, and communicate this confidence through the culture's core values, increase creativity among members (Kanter 1988). These findings are supported by a recent ethnography of a product design firm, IDEO, which creates new products by taking technologies from one industry and applying them in other industries where these technologies are unknown (Hargadon and Sutton 1997). At IDEO, employees are encouraged to create analogies between past technological solutions and current problems and to share them in brainstorming sessions. Further, employees are selected who have unique hobbies or skills that can be used to solve design problems.

Employees who have traits associated with creativ-

ity are more likely to thrive in organizations such as IDEO, which place an emphasis on creative performance. For example, employees produced the most creative work when they possessed the appropriate personal characteristics, were working on complex assignments, and were supervised in a supportive, noncontrolling fashion (Oldham and Cummings 1996). While the possibility that organizations can manage creativity through the use of a strong culture appears promising (Flynn and Chatman 2001), some worry that mechanisms of social control will stifle, not encourage creativity (Nemeth and Staw 1989). Future researchers might examine how organizations can achieve harmony and cohesion without sacrificing the flexibility and constructive conflict necessary for creativity and innovation. Many believe that creativity and innovation are the last sustainable competitive advantages and as such these issues will continue to generate a great deal of interest.

6. *Conclusion*

As theorists endeavor to develop a complete understanding of behavior in organizations, the analysis of both personal and situational factors, as conjoined units of behavior, will become increasingly fundamental to organizational studies. Person-situation interactions are much more complex than the simple addition of personal and situational characteristics, and these interactions may take a variety of forms. Some people are more responsive to situations than others, some situations can shape behavior to a greater degree than others, and some people have the unique capability to shape situations to their advantage or that of the organization. Furthermore, group members' personal characteristics may constitute the situational context as every individual responds to the personal or demographic characteristics of every other individual in the organization (Carroll and Harrison 1998, Tsui et al. 1992). These interactions are both complex and diverse: hence the field of organizational behavior must necessarily reflect this diversity. It will become increasingly important to observe these interactions over time. Since people and situations adjust to each other, cross-sectional research will not capture the dynamic interplay between the two. By pursuing interactional research over time, organizational behavior will increasingly evolve into a field that is as vibrant as the organizations it seeks to understand.

J. A. Chatman and J. A. Goncalo

Peptides and Psychiatry

Since the 1970s, much has been learned about the role of peptides in the central nervous system (neuropeptides) and behavior. Originally thought to be rare and relatively unimportant compared to the classical neurotransmitters, they are now known to be nearly ubiquitous and extremely important in brain function. Like the 'classical' small molecule neurotransmitters, neuropeptides function as chemical mediators of neuron to neuron communication. However, unlike such classical neurotransmitters, the neuropeptides have often been evolutionarily conserved to act both as local transmitter modulators and as endocrine hormones, thus mediating complex patterns of integrated behavior.

The role of neuropeptides in facilitating complex aspects of behavior makes them ideal candidates in understanding the neurobiological bases of psychiatric disorders. Whereas the classical neurotransmitter systems are involved in the neuronal circuitry mediating all behavior and pathology, the neuropeptide systems appear anatomically distributed, but functionally more limited. Thus these systems may allow an understanding of the physiology and pathophysiology of behavioral repertoires along with the ability to treat psychiatric disorders with more specific treatment modalities. This article will briefly review neuropeptide biology and function in general. Several specific examples of neuropeptides with known behavioral significance are discussed, allowing some generalizations to be made connecting physiological behavior to pathological disease states.

1. Neuropeptide Biology

Like the classical small neurotransmitters, neuropeptides also function as chemical mediators of neuron to neuron communication via presynaptic release onto postsynaptic receptors. Some neuropeptides serve their function primarily within the central nervous system (CNS), e.g., galanin and enkephalin. However,

other neuropeptides serve as both neurotransmitters and endocrine hormones via pituitary release to act on peripheral sites, e.g., oxytocin and vasopressin. Other neuropeptides serve as local neuromodulators within the brain but also as hormone-releasing factors in the hypothalamus–pituitary system, e.g., corticotropin-releasing factor and thyrotropin-releasing hormone. Finally, some neuropeptides appear to have distinct and separate roles in CNS and periphery, e.g., neurotensin and cholecystokinin.

1.1 Neuropeptide Production

The classical neurotransmitters (i.e., glutamate, GABA, dopamine, serotonin, norepinephrine, and acetylcholine) are formed from small molecule precursors in the cytoplasm, often stored at the terminals where the neurotransmitter is packaged into vesicle pools. Control of pool size is a function of enzyme concentration and precursor availability. In contrast, peptides are the direct products of mRNA translation, essentially small protein products. Most neuropeptides are between 2 and 40 amino acids in length. They are initially formed as larger precursor proteins (pre-hormones) by translation of mRNA into polypeptides that are then cleaved into various active smaller peptides. Within the cell body, vesicles of neuropeptides are packaged in the Golgi apparatus and then transported to the distal regions (axons and dendrites) of the neuron where they are released with neuronal activity. Control of neuropeptide availability is therefore largely a direct function of gene transcription and translation. Thus, change of neuropeptide expression occurs as a function of multiple hormonal and other modulatory influences on neuronal function.

1.2 Neuropeptide Release and Inactivation

Discovered as early as 1940 by the Scharrers, a husband and wife team, peptides are located in secretory granules (vesicles) at the neuronal terminal. Depolarization of the neuronal membrane leads to calcium influx locally, resulting in vesicle fusion with the membrane and release of peptide into the extracellular space. After release from presynaptic nerve terminals, the peptides diffuse across the synaptic cleft, binding to high affinity receptors on the postsynaptic membrane.

Termination of neuropeptide activity occurs when peptidase enzymes cleave the peptides into smaller fragments, disrupting their biologic activity. This is in contrast to small neurotransmitters that are removed from the synaptic cleft primarily by reuptake into the presynaptic terminal, with only modest breakdown by metabolic enzymes in the extracellular space. These

differences in inactivation generally lead to substantially longer periods of activity by the neuropeptides. Numerous peptidases have now been identified from endopeptidases to carboxypeptidases with differential specificities and different solubility vs. membrane-bound characteristics. These may differ among the different neuropeptide systems.

1.3 Neuropeptide Receptors

Neuropeptide receptors are generally of the G-protein coupled class of seven transmembrane receptors. Peptides released into the synaptic cleft activate these receptors via high-affinity binding and mediate internal signaling events via the cytoplasmic G-protein coupled effector. Activation of these receptors activates and inhibits a variety of second messenger systems and can result in cell firing, modulation of membrane threshold, phosphorylation and dephosphorylation events, and alteration of gene expression. These changes can thus have direct effects on the target cells or can modulate effects of other neurotransmitters. Furthermore, as in the hypothalamic-pituitary system, activation of hormone-releasing factor receptors causes release of other neuropeptides into the periphery, e.g., thyrotropin-releasing hormone activates release of thyroid-stimulating hormone from the thyrotrophs in the pituitary.

1.4 Colocalization of Neuropeptides and Classical Neurotransmitters

Neuropeptides are often found in neurons that also contain one of the small classic neurotransmitters. However, the neuropeptides and small neurotransmitters often have different dynamics of release and subserve different functions. For example, in some neurons with slow firing, release is limited to small neurotransmitter vesicles. With rapid burst firing and prolonged depolarization, however, the calcium concentration in the presynaptic terminal is significantly elevated, leading to release of neuropeptide vesicles in addition to neurotransmitter. Thus the different dynamics of release along with differential receptor activation allow these colocalized mediators to carry different functional signals in neuronal circuitry.

2. Behavioral and Psychiatric Aspects of Neuropeptides

The impetus for understanding neuropeptide biology since the 1970s has led to great advances in endocrinology and has had a significant impact on psychiatry. It is becoming increasingly evident that many

psychiatric disorders are associated with neuropeptide abnormalities. Alterations in specific neuropeptide-containing neurons have been shown in Alzheimer's disease, Parkinson's disease, Huntington's disease, mood disorders, anxiety disorders, eating disorders, and schizophrenia.

There are over 100 neuropeptides now identified and currently being scrutinized. This rapid expanse of knowledge cannot be summarized here. Therefore, a few examples of neuropeptide systems are discussed below which have known behavioral, physiological, and pathological significance. As with those discussed below, many neuropeptides have multiple roles in somatic sites, the central nervous system, and as hormonal mediators linking them. Understanding the physiologic role of these molecules will likely guide the understanding of pathophysiology and treatment of the psychiatric disorders in which they are involved.

2.1 Corticotropin-releasing Factor—Model of Integrated Stress Response

Corticotropin-releasing factor (CRF) was originally identified in crude form in 1955 and finally structurally identified in 1981 as a 41 amino acid peptide. It is the primary stimulant of adrenocorticotrophic hormone (ACTH) release from the anterior pituitary, initiating the hypothalamic-pituitary-adrenal (HPA) peripheral stress response. It clearly also functions as a putative neurotransmitter in the brain coordinating global responses to stressors. In higher organisms, CRF appears to mediate a complex behavioral program integrating the endocrine, immunologic, autonomic, and behavioral responses to stress.

CRF appears to be of crucial importance in many psychiatric disorders. Dysregulation of the HPA axis in major depression has been one of the most consistent findings in biological psychiatry since these abnormalities were first identified. As the field continues to understand the nature vs. nurture debate of psychopathology, the role of the endogenous stress response system in the stress-diathesis model of affective and anxiety disorders becomes paramount.

2.1.1 CRF, the physiologic mediator of stress. There is now abundant evidence that CRF and related peptides are the primary central nervous system (CNS) mediators of stress. Stress, *per se*, is generally defined as extraordinary demand on the organism or alterations in psychological homeostatic processes. Initially, the importance of CRF was thought to be primarily endocrine via activation of ACTH from the pituitary, with subsequent release of cortisol and other glucocorticoids from the adrenal gland. Since the 1980s, however, its role in the brain independent of the

HPA axis has been firmly established. Consistent with its role as a neurotransmitter mediating complex repertoires, CNS administration of CRF mimics many of the behaviors and autonomic responses seen with physiologic stress.

Neurons expressing and releasing CRF are located in neuroanatomic locations which are thought to be critical for the stress response, including areas of neocortex, limbic system, and midbrain. In the limbic system, the central amygdala and bed nucleus of the *stria terminalis* are regions of the so-called 'extended amygdala' believed to be involved in stress and anxiety. CRF neurons from these regions project to many midbrain and brainstem sites mediating internal stress responses. The *locus coeruleus* and the *raphe nucleus* in the midbrain receive these CRF projections, influencing the activation of norepinephrine and serotonin circuits, respectively. Thus stress activation of the CRF system can disrupt attention and vigilance, concentration and memory, sleep and wakefulness via these transmitter systems, and it is likely involved in their abnormal functioning in mood and anxiety disorders.

There are multiple experimental paradigms further implicating the central CRF system as the prime mediator of the acute and prolonged stress response. Rodents administered CRF directly into the CNS show decreased reproductive behaviors, altered sleep, increased grooming, increased signs of despair, increased neophobia, and altered appetite, all of which mimic the behavioral stress response. Furthermore, rodents raised with early life stress (primarily maternal separation) hypersecrete CRF from the hypothalamus and amygdala, both during the stress and later as adults.

Administration of CRF into the CNS of nonhuman primates elicits many signs of behavioral despair including increased vocalization, decreased exploration, and increased huddling. These effects are reversed by CRF receptor antagonists, as are the behavioral consequences of environmental stress. Consistent with these experiments are early studies of maternal deprivation in young Bonnet macaque monkeys. These experimental animals exhibited sustained behavioral despair with decreased locomotion, decreased exploration, and altered food intake, similar to those animals with centrally administered CRF. These animals persistently exhibited a prolonged activation of the HPA axis with elevated cortisol and ACTH peripherally.

Stress exposure to maternal-infant dyads without separation appears to have similar long-term effects. Young Bonnet macaques raised in naturalistic settings by mothers with an unpredictable food supply showed increased signs of anxiety compared to those with a predictable food supply. These symptoms were accompanied by elevated CSF CRF concentrations. Remarkably, the grown youngsters consistently showed continued signs of anxiety and affective

disturbance after removal from these stressful living constraints, and their CNS CRF and HPA axis activity remained hypersensitive to other stressors later in life.

2.1.2 CRF, the pathologic mediator of depression and anxiety. The preceding paragraphs suggest that the CRF system must play a critical role in the development of stress-related disorders. It is now becoming increasingly clear that depressive and anxiety disorders have significant inheritable and environmental components. The likelihood of an individual to develop an affective disorder is related to genetic vulnerability in addition to his or her biologic capacity to respond to stress. The experiments above suggest that this capacity is somewhat plastic, influenced by extent of early life stress. Multiple lines of evidence have shown that CNS CRF systems are altered in mood and anxiety disorders.

Many studies have reproduced the early findings that CRF CSF concentrations are elevated in depressed individuals compared to healthy comparison subjects, and that the levels resolve with resolution of the depressed state. Dysregulation of the HPA axis also continues to be validated. The CRF stimulation test (depressed patients show a blunted ACTH response) along with the Dexamethasone Suppression Test (depressed patients do not suppress cortisol) as well as the combined Dex/CRF test developed by Holsboer remain very sensitive tests of major depressive disorder. Furthermore, MRI and CT evidence has revealed increased pituitary and adrenal gland size in depression, consistent with hypersecretion of CRF and ACTH, respectively.

The role of CRF in anxiety disorders is also likely critical, though less well established than in depression. In animal models, direct CNS CRF administration is markedly anxiogenic, and conversely CRF receptor antagonists are anxiolytic. In experimental models, alprazolam, a short acting benzodiazepine, leads to decreased *locus coeruleus* CRF concentrations after acute administration, an effect which may mediate its anxiolytic action. Patients with post-traumatic stress disorder (PTSD) also exhibit elevated CRF concentrations in CSF and a blunted ACTH response to CRF challenge. However, they are hypocortisolemic and exhibit supersuppression to dexamethasone, suggesting that they differ from patients with depression.

In summary, the effects of CRF administration mimic acute anxiety and chronic depression, CRF₁ receptor antagonists block some of these symptoms in model systems, and patients with depressive and anxiety disorders show alterations of the central and peripheral CRF-HPA system. These data are nicely linked to a growing understanding of the developmental role of stress on the CRF system and its possible *sequellae* later in life. This allows a reformulation of the stress-diathesis model: early untoward life

events associated with development of depression and anxiety in adulthood give rise to long-lasting changes in CRF neurons, thus increasing the individuals' vulnerability to affective and anxiety disorders. See *Depression; Anxiety and Anxiety Disorders*.

2.2 Oxytocin and Vasopressin—Models for Complex Behavioral Regulation

Oxytocin (OT) and vasopressin (AVP) are members of the same nine amino acid class of peptides and have similar behavioral effects. Due to their interactions and similar effect on behavior, they will be considered together here. These peptides are best characterized in terms of organizing a complex behavior, that of social affiliation. This includes reproductive behavior, parental behavior, parent–child bonding, and grooming—sitting together behaviors in nonhuman primates. They are recently evolved and mediate many mammalian-specific reproductive and social behaviors. However, there are profound species differences in receptor expression, which in some cases mediates species-specific sets of behavior.

2.2.1 Oxytocin and vasopressin mediate social interaction. The best known peripheral effects of OT are facilitation of lactation–milk ejection, and uterine contraction during labor. AVP serves in the periphery primarily to regulate blood pressure and plasma volume. These functions are mediated via the magnocellular neurons projecting from the paraventricular nucleus (PVN) of the hypothalamus to the posterior pituitary where the peptides are released into the general circulation. Central effects are mediated via the PVN projection of parvocellular neurons to areas of the limbic system, neocortex, and autonomic areas of the brainstem. These central effects include modulation of reproductive behavior, parental behavior, infant attachment, and other prosocial effects.

One of the best studied models of affiliation is the formation of pair bonds. Multiple lines of evidence have demonstrated that in several rodent model systems, OT and AVP are critical for these behaviors. The prairie vole has been an excellent model for these studies because these animals are highly affiliative, show strong monogamous behavior, frequent physical contact, nest building, and shared parental care. OT in females and AVP in males appears to be responsible for formation of partner preference. In this species, mating facilitates pair bond formation, and OT and AVP are released centrally with mating. OT antagonists in females and AVP antagonists in males block formation of the partner preference, whereas the respective agonists administered centrally facilitate partner preference in the absence of mating. These results suggest that these peptides are both necessary

and sufficient for this aspect of pair bonding. Furthermore, a closely related species, the montane vole, shares many similar nonsocial behaviors with the prairie vole, but they are generally isolative, are clearly not monogamous, and males show little parental care. The critical difference in species appears to be the regulation of the OT and AVP receptor distribution in the brain. For example, the prairie vole has OT receptors in regions important for reward (*nucleus accumbens* and prefrontal cortex), whereas the montane vole shows primary distribution in the lateral septum, possibly responsible for the peptide's effect on self-grooming, but poor socialization. This is supported by evidence that centrally administered AVP increases affiliative behavior in the monogamous prairie vole, but not the montane vole. Furthermore, transgenic mice expressing the AVP receptor in the prairie vole brain distribution pattern results in a prosocial response to centrally administered AVP.

Parental behavior and infant attachment also appear to be dependent on OT and AVP systems. Parturition is associated with significant shifts in maternal behavior in some species, including relentless nest building, licking, grooming, and protection of the pups. These behaviors are blocked by central administration of OT receptor antagonists. Neonatal voles crave social contact with 'distress calls' vocalized in as early as five-day old pups with maternal separation. Centrally administered OT in eight-day old pups results in significantly reduced distress calls, but no evidence of sedation or other behavioral change, suggesting that OT influences the maternal separation response.

Evidence for other social behaviors mediated by these systems include increased levels of social grooming by centrally administered OT or AVP, and the correlation of decreased plasma OT with increased social stressors in primates. Finally, there is an interesting cognitive response to these peptides. Oxytocin appears to facilitate extinction and attenuates passive avoidance. It is hypothesized that these effects may allow the relinquishing of normal social avoidance to establish critical social bonds.

In summary, oxytocin and vasopressin have important roles in the initial affiliative and territorial stages of reproductive behaviors that are dependent on gender and species, along with influences on parental, attachment, and group social behavior. These neuropeptides appear to alter the affective processing of social stimuli via regionally specific regulation of neuropeptide receptors.

2.2.2 Possible roles for oxytocin and vasopressin in psychopathology. The data for these neuropeptides in animal affiliation suggest that they might also be important in human psychopathology in which relationships or social attachments are abnormal. Measures

of CSF OT and AVP concentrations have yielded inconsistent results in patients with schizophrenia or major depressive illness, though only a handful of studies have been performed. However, post mortem studies have suggested significant changes in several pathological processes. Significant increases in the number of hypothalamus AVP and OT cells have been found in post mortem studies of depressed subjects. Post mortem studies also revealed a > 40 percent decrease in OT cells in the Prader–Willi syndrome, a genetic disorder notable for obesity, mental retardation, hyposexuality, and inappropriate behavior. Several studies have consistently found elevated OT concentrations in OCD subjects, along with normal to elevated concentrations of AVP. One possible explanation for a role in OCD would be the relationship between OT and AVP and grooming behavior and their role in extinguishing avoidant behavior.

Most interesting would be the human disorders along the schizoid spectrum to autism, in which limited interpersonal skills and social impairment are paramount. With autism, the onset is clearly developmental prior to three years old, with most families noting decreased social interest in the first months of life. It is clearly genetically transmitted with monozygotic twins having approximately 36–91 percent concordance, compared to < 0.1 percent in the general population. In one study of autistic children, plasma OT was about half that of age-matched controls. Furthermore, autistic children failed to show the normal developmental increase in OT compared to controls. Although many clinical studies remain to be done (no study of CSF samples is yet reported), the preclinical data suggest that the OT and AVP systems are critical for normal social behavior and memory. Studies are also yet to be reported on the schizoid and avoidant spectrum disorders, but given the specificity of the OT and AVP systems, one suspects that there may be some abnormalities. Given the complexity of OT and AVP receptor gene regulation with known polymorphisms in humans, one could hypothesize that some aspects of social temperament are genetically influenced by the precise expression patterns and regulation of these behaviorally relevant peptides and receptors.

2.3 Cholecystokinin and Neurotensin—Models of Complex Neuromodulators

Cholecystokinin (CCK) and neurotensin (NT) are unrelated, evolutionarily conserved peptides of 8 and 13 amino acids, respectively. They are discussed in this section as examples of the large group of peptides that less clearly integrate a specific behavioral repertoire. They are found in numerous tissues and subserve many different roles including local paracrine, endocrine, and neurotransmitter functions. However,

their similarities are intriguing. They share endocrine functions regulating feeding behavior and induction of satiety in the periphery along with neuromodulatory functions interacting with the primary reward and appetitive circuitry in the central nervous system. Furthermore, there is mounting evidence that they each may play significant roles in the pathophysiology of schizophrenia, and in the case of NT in the mechanism of action of antipsychotic drugs.

2.3.1 Cholecystokinin and neurotensin involvement in feeding, autonomic regulation, and nociception. CCK was one of the first of the gastrointestinal hormones discovered and one of the most abundant neuropeptides in the brain. In contrast, NT was initially discovered from bovine hypothalamic extracts and later found to be an important gastrointestinal hormone. In the periphery, CCK and NT are each released by the small intestine shortly after a meal, and remain elevated in the plasma for several hours. They both stimulate pancreatic and biliary secretion along with modulating small and large intestinal motility. Although they do not cross the blood–brain barrier, they have an apparently conserved function in the CNS. They are both thought to have a role in mediating satiety and inhibiting feeding within the CNS.

They share the property of regulating autonomic and nociceptive information from the midbrain to the cortex. CCK and NT released in the midbrain have been shown to directly modulate excitatory visceral transmission through the parabrachial nucleus to the thalamus. Furthermore, both have been shown to exert potent analgesic effects when injected directly into the CNS. Thus they appear to be involved in regulating sensory information representing the internal state of the organism. Modulation of autonomic outflow is evident by their role in regulating vascular tone and thermoregulation.

2.3.2 Cholecystokinin and neurotensin modulation of dopaminergic systems. In addition to the above functions, CCK and NT appear to be integrally involved in modulating the dopaminergic systems within the brain. Although they are co-localized with other neurotransmitters and modulate serotonin, acetylcholine, and other neuropeptides in some areas, there appears to be a consistent role for these peptides in modulating dopamine circuits. Dopamine (DA) is found in three principle pathways: the mesolimbic/mesocortical pathways involved in motivation, reward, and cortical processing; the nigrostriatal pathways involved in mediation of locomotor movements; and the tuberoinfundibular pathways controlling pituitary release of prolactin. The role of CCK

and NT in modulation of the mesolimbic circuitry originating in the ventral tegmental area (VTA) is of particular interest. Within this mesencephalic nucleus, NT and CCK are co-localized in many dopaminergic neurons that project to the *nucleus accumbens*. NT and CCK are also found in cortical neurons, likely modulating the terminal projections of dopaminergic axons.

Both NT and CCK induce an initial increase in firing rate of dopaminergic neurons when released into VTA, along with an increase in DA release in the *nucleus accumbens*. This increased firing appears to be due to inhibition of D2 autoreceptors by decreasing affinity for DA. This change is thought to occur via intracellular transduction mechanisms and allosteric receptor-receptor interactions between the D2 receptor and the CCK and NT receptors. In contrast, at high doses and with chronic treatment, these peptides significantly decrease spontaneous activity of dopaminergic firing via depolarization inactivation. Thus, these neuropeptides have the ability, *in vivo*, of modulating dopaminergic function at the level of the midbrain and in the projection areas.

Whether the varied roles of feeding behavior, autonomic and nociceptive regulation, and dopaminergic modulation are functionally related is unclear. Some have speculated that these peptides were evolutionarily involved in the primary functions of feeding and feeding regulation. The CNS must be able to organize homeostatic mechanisms around this critical behavior including cardiovascular tone and temperature regulation because much of the blood volume goes to the gut postprandially. Relative analgesia postprandially might be crucial for maintaining the primary function of digestion. Finally, as complex behavior evolved, these neuropeptide systems may have served to couple the primary reward of feeding to the central motivation/reward circuitry.

2.3.3 Cholecystokinin, neurotensin, and schizophrenia.

The underlying pathology in schizophrenia remains unknown. The empirical observation that all effective antipsychotics were also dopaminergic antagonists contributed to the original DA hypothesis. However, more recent research has failed to find consistent abnormalities within the dopaminergic system, *per se*, in schizophrenic patients. Additionally, evidence for disturbances in the glutamatergic, GABA-ergic, serotonergic, and cholinergic systems have accrued. One way to reconcile the vast data is that the activity of multiple neurotransmitter systems may be altered via a dysregulation of normal activity. Because neuropeptides are known to play an important role in neurotransmitter modulation, these systems have received increasing attention as both possible mediators of the pathophysiology in schizophrenia as well as potential targets for novel therapeutics.

Although several neuropeptide systems may contribute to the abnormal circuitry in schizophrenia, the majority of data point to NT and CCK as being the most likely candidates of the known neuropeptides. Their role as modulators of the dopaminergic system was outlined above. Additionally, both the serotonergic *raphe nuclei* and brainstem cholinergic nuclei are innervated by peptidergic neurons, especially NT. Within the DA system, these neuropeptides mimic the effects of antipsychotic medication in their acute activation of the VTA dopaminergic neurons and in their chronic inactivation of these neurons. Furthermore, treatment with an NT receptor antagonist appears to mimic atypical antipsychotics in that chronic administration leads to decreased VTA firing, with no effect on the nigrostriatal system. This effect is thought to be mediated via feedback onto the VTA from the prefrontal cortex where local injection of the NT antagonist has the same effect. This would also be consistent with newer theories of schizophrenia which invoke disruption of large mesolimbic-cortical activation loops as mediating the pathophysiologic events.

Behavioral studies with centrally administered NT and CCK also mimic effects of typical and atypical antipsychotic medication. They both decrease stimulant-induced locomotion and spontaneous locomotion. They also decrease avoidance, but not escape, responding in a conditioned avoidance paradigm. Perhaps most importantly, they both appear to effect models of sensorimotor gating, which is becoming increasingly accepted as a critical objective symptom of schizophrenia. The hypothesized decreased ability of these patients to screen for appropriate sensory data may lead to 'involuntary flooding' of indifferent sensory input. This might lead to cognitive abnormalities, thought disorganization, and the positive symptoms (hallucinations and delusions) which are hallmarks of schizophrenia. Prepulse inhibition (PPI) of the startle reflex (defined by decreased startle to sound if preceded by weaker sound), and latent inhibition (LI) (reduced associative learning if subject is pre-exposed to stimulus), are the two most common measures of sensorimotor gating. In humans, PPI and LI are disrupted in schizophrenic patients, and are normalized in some studies of schizophrenics treated with antipsychotic medication. In animal models, dopaminergic agonists and other psychomimetic compounds disrupt PPI and LI, and these are returned to normal with antipsychotic treatment. NT and to a lesser extent, CCK, also clearly modulate PPI and LI in animal models. These results provide substantial evidence for the role of NT and possibly CCK in the circuits that are affected by antipsychotic medication.

Finally, there is significant evidence of abnormal regulation of CCK and NT in the CNS of schizophrenic patients. Although no consistent changes have been found post mortem with NT levels, NT receptor binding has reproducibly been found to be decreased

in some cerebrocortical regions in schizophrenia. Concentrations of NT in the CSF are reproducibly decreased in nonmedicated schizophrenics. These levels return to normal with effective treatment, and lower NT concentrations have been correlated with more severe psychopathology, particularly negative symptoms. Similar findings of NT abnormalities have not been found in affective disorders, anorexia, or Alzheimer's disease, suggesting some specificity of the findings in schizophrenia. Post mortem CCK levels have been consistently decreased in cerebrocortical and limbic regions of schizophrenic subjects, but CSF CCK changes have not been as reproducible. See *Schizophrenia, Treatment of*.

3. Summary

Since the 1970s, the biology and behavioral roles of many neuropeptides have been elucidated. They have moved from a position of relative unimportance in behavioral neuroscience to pre-eminence. In their roles as neurotransmitter and neuromodulator, paracrine and endocrine hormone, individual neuropeptides may at times subserve different functions in the CNS and periphery. However, many neuropeptides share a conserved function organizing different neural systems with the periphery in behaviors important for coordinated activity of the organism.

Corticotropin-releasing factor is essential in the physiologic mediation of stress, and likely critical in the pathophysiology of depression and anxiety. Oxytocin and AVP subserve many social roles from bonding to parental behavior, and they may underlie some pathologic processes involving socialization such as autism. Finally, the peptides NT and CCK have similar roles in feeding, autonomic and analgesic regulation, and DA modulation in the brain. Their dysfunction may contribute to the pathophysiology of schizophrenia.

The knowledge of these neuropeptide systems in psychopathology provides wonderful opportunities for future rational therapeutic approaches. CRF₁ receptor antagonists show great promise in preclinical and early clinical trials for the treatment of depression and anxiety. Oxytocin has been found to improve socialization in some experiments of schizophrenic patients and may provide future hope for autistic disorders. Neurotensin and CCK receptor agonists provide important targets for future system-directed treatment options in schizophrenia. In summary, via their role in the organization of behavioral repertoires, neuropeptide systems may ultimately elucidate mechanisms and provide novel treatment options for many psychiatric diseases.

Perception and Action

Perceiving without acting is hardly possible: scrutinizing an object visually presupposes directing the eyes at it, which sometimes involves moving the head or even

the whole body; a tactile investigation of an interesting object requires moving the fingers across its surface; and localizing a sound source is much easier when moving the ears and head (Dewey 1896). Likewise, acting without perceiving makes no sense; after all, actions, defined as goal-directed behavior, aim at producing some perceivable event—the goal. Performing an appropriate action requires perceptual information about suitable starting and context conditions and, in the case of complex actions, about the current progress in the action sequence. Thus, perception and action are interdependent. However, in the course of evolution humans have developed several ways to relate action to perception, ranging from simple and rigid stimulus–response (S–R) reflexes shared with many species to flexible and adaptive behavioral rules that can be tailored on the spot to the situation at hand.

1. Reflexes

In most species, behavior is triggered by the present situation and, thus, directly reflects the animal's immediate environmental conditions. Such reflexes can also be observed in humans, especially in infants, but here they constitute a negligible part of the behavioral repertoire. Interestingly, however, even reflexes already show the close mutual relationship between perception and action. Perhaps the best demonstration of this relationship is provided by the orientation reflex, which we experience when encountering a novel and unexpected event. On the one hand, this reflex inhibits ongoing actions and tends to freeze the body—a prime example of a stimulus–triggered response. At the same time, however, it draws attention towards the stimulus source by increasing arousal and facilitating stimulus-directed body movements. That is, the novel stimulus triggers actions that lead to a better perception of itself, thus producing a full S–R–S cycle.

Even though reflexes themselves represent a relatively inflexible way to coordinate perception and action, some researchers have suspected them to provide the basis for voluntary action (Easton 1972). For instance, the tonic neck reflex, an asymmetric pose observed in newborns with head and arm extended to one side and arm and leg flexed on the other, might facilitate the development of eye–hand coordination. Likewise, the stepping reflex, in which babies move their feet in succession when coming in contact with a solid surface, might underlie our ability to walk.

2. Associations

Human behavior (and that of other higher species) is surely much more flexible than exclusive control by reflexes would allow. Not only can we learn to react to

particular environmental conditions and situations in a certain way, we also can unlearn what we have acquired and learn new relationships between situations and actions. Our ability to associate actions with stimulus conditions was the major topic of American behaviorism around 1890–1940, when most of the basic principles of S–R learning were empirically established. In particular, stimuli and responses become associated only if they co-occur in time, if there is at least some degree of contingency between them, and if the response is judged to be appropriate (Thorndike 1927). Although the empirical approach and the theoretical language of behaviorism has long been abandoned, its results still have a major impact on modern connectionism, the attempt to model psychological phenomena by means of artificial neural or neurally inspired networks on computers or in robots.

A major objection against the behavioristic approach to S–R learning relates to the assumed role of action outcomes. In behavioristic theories, the outcome of a given action is only judged regarding its hedonic value: a positive evaluation results in strengthening the association between the action and its antecedents whereas a negative evaluation weakens the association. However, whether it feels good or bad, the outcome of an action also informs the actor about its consequences, that is, about what he or she can achieve by performing it (Tolman 1932). And as actions aim at producing intended outcomes, perception–action learning should not be restricted to forming stimulus–response associations but comprise response–effect associations also. Indeed, studies reveal that humans (and also rats and pigeons) do acquire very stable associations between their actions and the consequences that these actions produce. Moreover, there is evidence that these associations play a major role in the control of voluntary action. That is, people control their overt behavior by forming or reactivating perceptual representations of intended goal events, which through learning have become associated with the motor patterns that have been—and must be—carried out to reach them.

3. Rules

The ability to learn new relations between environmental conditions and appropriate behavior provides an enormous gain in flexibility for an individual in allowing it to adapt to environmental change. Yet, learning and relearning take time and require at least some experience with a given new condition—it is thus necessarily reactive and, in a way, conservative in reflecting what one has become used to. Indeed, many forms of human behavior show these characteristics, as witnessed by the difficulties of introducing new behavioral patterns regarding, say, women, ethnic minorities, or the use of environmental resources.

Nevertheless, there are many instances where people can switch between different reactions to the same stimulus conditions on the spot, and hence more or less independently of the amount of experience with the situation. For example, even though one may have used one route to go to work 1,000 times already, it is easy to take an alternative route from one day to another, without having to unlearn the old habit or to learn the new one, and although the fact that in the case of absent-mindedness one might again go by the old route shows that the overlearned associations still exist. Therefore, people must be able to choose deliberately among alternative ways to relate environmental situations to their actions, that is, to select one out of many possible S–R rules, and behave accordingly.

The interplay between overlearned S–R associations and the voluntary implementation of intentionally selected S–R rules ('habit' vs. 'will') was a major issue in the psychological literature between 1870 and 1935, and Narziss Ach (1935) was the first to study this interplay empirically in a systematic way. In his 'combined method' he first had subjects build up new, strong associations between nonsense syllables and one type of action, and then asked them to perform another than the practiced action to the same stimuli. The resulting increase in reaction time and errors as compared with actions with neutral stimuli was taken to represent the individual 'will power' needed to overcome the previously acquired habits. After many years of neglect, the issue of how people implement and switch between alternative S–R rules received renewed interest during the 1980s and 1990s, especially in experimental and neuropsychology (Monsell and Driver 2000). The (still preliminary) results of this research provide new insights into the relationship between, and the control of, perception and action. As one would expect, the implementation of S–R rules takes effort and time. If people are to apply several sets of S–R rules concurrently, or in short succession, their performance is impaired and more error prone. In particular, they will sometimes apply the wrong rule or apply the right rule at the wrong time, especially if effort and attention deteriorate. However, even under ideal conditions, intentional control is not absolute. That is, voluntarily implementing a particular rule does not exclude or prevent contributions from overlearned S–R associations (habits). Therefore, although any S–R rule can be implemented in principle, those rules are easier to implement and to apply if they are in accordance with natural S–R relations, acquired S–R associations, and previously implemented S–R rules than if not. For instance, performance is better if stimuli and responses have features in common than with arbitrary S–R relations, so that pressing a left or right key, or turning to the left or right, is easier if signaled by the location of a stimulus that also appears on the left or right side than by the color, shape, or meaning of a stimulus.

The ability to implement and switch between the most arbitrary S–R rules allows for the highest degrees of behavioral flexibility but it is at the same time costly in terms of attentional resources. Therefore, it makes sense to see intentional rule implementation and the more automatic guidance by overlearned S–R associations as mechanisms that complement each other: implementing and acting out the same rules repeatedly and with sufficient success provides the basis for forming increasingly stronger associations between the corresponding environmental conditions and actions, in this way transforming rules into habits.

4. Plans

In one sense, perception and action are interdependent to a degree that makes it difficult to say where action ends and perception begins—just think of the eye-movement example. In another sense, however, evolution has provided humans with the important ability to temporally decouple our actions from perception. That is, actions can be planned, prepared, and scheduled long before their environmental trigger conditions occur. Although we are only beginning to understand how action planning works, there is evidence that it can be likened to self-automatization.

At least three phases of planning can be distinguished. First, the features of the intended action effect (i.e., the goal) need to be specified, such as the direction or end location of a reach, and the effector to be used. Next, the features belonging to one plan are integrated (i.e., their cognitive representations are temporarily coupled), to avoid confusing features belonging to different, concurrently maintained action plans. This integration process will often involve linking the plan to its anticipated trigger conditions, and hence to representations of the event that is intended to trigger the planned action. That is, planning comprises anticipating both perceptual and action events. Accordingly, planning an action changes our perception. For instance, after having planned a particular action, action-related objects and events are more salient and more easily processed, action-related features of objects are more conspicuous than other features, and objects appearing at action-related locations catch more attention than others.

The final step of planning consists of initiating the planned action. Initiation may be triggered internally, such as when a plan is carried out immediately after construction, or externally, such as when the anticipated trigger event is perceived. Interestingly, this last step does not seem to underlie overly strict cognitive control. For instance, internal initiation is more or less indifferent to the content of the plan or the progress of planning, and externally triggered plans can be seen to be called up even under inappropriate conditions or at the wrong point in time. Thus,

planning is like automatizing oneself by means of delegating control to future, often environmental, events.

B. Hommel

Perception and Cognition, Single-/Multi-neuronal Recording Studies of

Recording of isolated single neurons from brain provides a means of estimating the relationship between an animal's behavior and the activity of the brain region from which the neuron was recorded. In this manner, neurophysiologists seek to explain all behaviors in terms of neural activity, and pair all neural activity with some perceptual, behavioral or cognitive event. Thus, the ultimate goal of neural recording and analysis is to determine how activity within a brain area relates to behavioral and/or cognitive events, in essence, seeking to answer the question: 'What do neurons encode?' This question is answered in part by recording and analyzing one neuron at a time, but there are additional character-

istics of encoding which can only be answered by examining the interactions between neurons which likely underlie the overall activity of a brain region. The purpose of both single and multineuron recording, thus, is to obtain a more representative view of the neural activity in a particular brain region (Singer 2000).

Single and multiple neuron recordings are particularly powerful when applied to experiments in which the brain must form some neural 'calculation' in order to make the appropriate response. This can be manifested on many levels, from the purely mechanical, such as integration of multiple inputs in a simple neuronal circuit, to complex behavioral responses dependent on an animal's ability to 'remember' prior stimuli. Inasmuch as the recorded neural activity reveals a pattern that correlates to the cognitive process, the neural activity can therefore be considered to 'encode' information related to the process. This does not necessarily mean that the neural pattern is essential to cognition, but that the neural activity suggests information, which is available to the brain during cognition.

1. Single vs. Multiple Neuron Recording

Single neuron recording has revealed the function of many brain areas in terms of stimulus and response. For example, Hubel and Wiesel (1962) mapped columns of neurons in the occipital cortex that responded to specific visual stimuli. The identification of these 'ocular dominance columns'—in which successive columns responded to incremental rotations of a bar of light, and alternating regions mapped the left vs. right visual fields—were critical to understanding how visual information was encoded by the brain. Similarly, the identification of 'place cells' in hippocampus—neurons that fire only when the subject is in fairly limited regions of its environment (O'Keefe and Dostrovsky 1971), provided a correlation between neural activity and behavior, even if the exact purpose of that activity is still being debated. Single neuron recording has thus been used to identify the type of information processed by different brain areas, not just the five senses, but also control of muscles, attention, and memory. To this end, the brain has been mapped anatomically and, to a certain extent, neurophysiologically.

Broader questions of function and cognitive processing are difficult to answer with only single neuron recordings. In essence, all neurophysiological experiments use multiple neuron recording, since the activity of a single neuron is not necessarily representative of that brain area. Instead, many single neurons are recorded, then analyzed to see if a pattern is detected which is representative of neural activity in that region. As long as single neurons are recorded under con-

ditions that control variability between recording sessions, it is possible (within limits) to treat the collection of neural recordings as if they had been recorded simultaneously. Thus, single neurons are assembled in an 'ensemble' that represents the activity of multiple neurons from a single brain area. In this manner, Georgopoulos et al. (1986) observed that the activity of ensembles of neurons recorded from primate motor cortex predicted the direction of limb movement prior to actual movement. In this study, many neurons were recorded that exhibited different 'preferred' directions for limb movement. When the pattern of firing across neurons was analyzed, it was found that the direction of movement was represented by specific firing patterns prior to the actual movement. However, since the conditions under which two single neurons are recorded cannot be identical, the effect of those subtle variations on neural firing cannot be controlled. In addition, the activity of single neurons may be controlled by multiple stimuli, in which case a behavioral correlate may be shared or distributed across many neurons.

Recordings of multiple simultaneous neurons have played an important role in many exciting recent discoveries. Deadwyler and Hampson (1997) showed that patterns of neural activity in hippocampus predicted behavioral error in a short-term memory task. Laubach et al. (2000) similarly demonstrated that activity patterns in neocortical neurons predicted behavior as animals learned a motor task. Skaggs and McNaughton (1996) showed that during sleep, hippocampal ensembles 'played back' temporal firing patterns between neurons. The replayed patterns were identical to patterns generated by the animal's exploration of its environment during the waking state. In addition, Chapin et al. (1999) recently demonstrated direct neural control of a robotic arm by neural signals recorded from rats. The researchers detected patterns of neural activity in motor cortex that preceded limb movements required to operate the robotic arm. By programming a computer to detect the pattern in real-time, the computer was able to operate the arm without requiring the animal to move its limbs. These recent results indicate rapid progress toward goals of better understanding the relationship between the activity of neurons and the cognitive functions of the brain.

2. Recording Many Neurons

Multiple neuron recordings not only rapidly increase the total number of neurons characterized, but also allow examination of interactions between neurons that may be critical to cognitive processing. Information may simply be encoded as the mean amplitude of firing across neurons at a given point in time, or as correlation between neurons (von der Malsburg 1994), or as part of coherent oscillations between neurons

(Singer and Gray 1995). No matter how the conditions are controlled during single neuron recording, interactions between neurons cannot be determined unless neurons are recorded simultaneously. The major advantage, therefore, of recording from multiple neurons in any brain area, is the potential for deciphering the codes that a brain area generates during cognitive or behavioral responding. The techniques used to record and analyze the multineuron data are critical, and not all types of multiple neuron analyses are appropriate in all cases. Misapplication of an ensemble technique can at best misrepresent the data, or at the worst lead to unworkable models of brain action. Several common uses of multiple neuron or ensemble analyses are examined below.

2.1 Techniques for Multineuron Recording

The ionic currents and action potentials generated by neurons produce changes in the electrical potential of the environment surrounding the neuron. These extracellular potentials are volume-conducted through the electrically-conductive extracellular fluid, and can be detected by electrodes that are either in contact with tissue or the cerebrospinal fluid. Skull surface or brain surface electrodes detect summed electrical activity resulting from the action potentials produced by millions of neurons throughout the brain, with no differentiation into single neurons. A glass pipette electrode will record neural activity from a region hundreds of microns in diameter; however, as above, the recorded neural activity is difficult to resolve into single neuron action potentials. Isolation of single neuron activity is possible with metal microelectrodes made from electrically conductive, but nonreactive material, such as tungsten, platinum-iridium, or stainless steel. Such electrodes are constructed with tip diameters approximate to the soma diameter of the neurons to be recorded and are insulated everywhere except at that tip. Sharp electrode tips ($1\ \mu\text{m}$) allow the electrode to be inserted with minimal tissue damage and allow the tip to be insinuated close to one neuron. In addition, the high impedance (resistance) of the tip ($> 1\ \text{M}\Omega$) ensures that electrical potentials from more distal neurons are attenuated compared to potentials generated by proximal neurons. More recent developments have shown that stainless-steel wires with tips up to $25\ \mu\text{m}$ and tip impedances of $100\ \text{k}\Omega$ are capable of isolating single neurons if left implanted for days or weeks (McNaughton et al. 1983, Deadwyler and Hampson 1997). Single neuron action potentials are identified by biphasic waveform (typically ± 10 – $100\ \mu\text{V}$ amplitude, 500 – $1000\ \mu\text{s}$ duration). As long as the electrode tip is not moving relative to the neuron being recorded, each action potential generated by a single neuron should be the same. Therefore, the activity of a single neuron is isolated by identifying and recording all action potential 'spikes' with the

same characteristic duration and amplitude. Multiple single neurons can be identified from a single microelectrode by further identifying similar spikes from all those rejected, or by using multiple microelectrodes.

2.2 Types of Multiple Neuron Recording Electrodes

The simplest multiple electrode is a bundle of metal microelectrodes, of similar size and shape, with tips positioned to record from within a restricted area. These electrodes can contact each other without compromising recording ability, since they are insulated everywhere except at the tip. The advantage of microelectrode bundles is the large number of recording sites in a small area, the disadvantage is that there is no means of identifying where any one electrode tip is located. When electrode location is desired, arrays of microelectrodes can be used. The electrode tips are spaced in a pattern, so that each tip records from a separate, identified site. Another form of bundle electrode is the stereotrode or tetrode consisting of two or four wires twisted to keep all electrode tips in close proximity. The close proximity of recording tips on stereotrodes and tetrodes allows the recording of neurons on more than one wire, improving the ability to isolate single neurons. Finally, as stereotrodes and tetrodes can be constructed as arrays, to provide all of the benefits of both electrode types.

2.3 Discrimination and Identification of Multiple Neurons

As stated above, the essential principle of single neuron isolation and identification is the fact that the action potential from a given neuron should always be the same amplitude and duration. Thus, action potentials with the same waveform characteristics, likely were generated by the same neuron. The first technique for identifying single neurons recorded from microelectrodes is to sort the extracellular action potentials by waveform. Under some circumstances, notably when recorded from dense monolayers of neurons, two neurons may be equidistant from the electrode tip, and hence produce action potentials of similar sizes and shapes. Stereotrodes and tetrodes were developed to identify single neurons under these conditions (McNaughton et al. 1983), since it is unlikely that both neurons would be equidistant from both electrodes in a stereotrode, or from all four electrodes in a tetrode. By comparing the action potential waveforms simultaneously recorded at all electrode tips, it is possible to 'triangulate' and separate neurons that may have appeared the same to a single microelectrode.

Statistical techniques are also used to ensure that the action potentials recorded on single or multiple microelectrodes originate from a single cell. The intervals between action potentials of a randomly firing single neuron (the neuron's 'spike train') should be a *Poisson* function. A plot of the interspike-interval

(i.e., between action potentials) should be similar to a graph of the *Poisson* probability distribution. In addition, autocorrelation of the spike train should reveal a symmetric distribution, with no firing within the time interval equal to the action potential refractory period for that neuron. Uniform interspike-interval distributions, or spikes occurring during the refractory period indicate a failure to isolate recordings into single neuron data (see Nicolelis 1999). These analyses, plus consistency in behavioral correlation, cross-correlation between neurons, and stability of action potential waveforms over an extended time (or multiple days) all indicate satisfactory identification of the single neuron (whether recorded with single wires, stereotrodes or tetrodes) and thus support the recording of multiple single neurons from bundled or arrayed microelectrodes.

3. Analysis of Multiple Neuron Recordings

The basic method of multiple neuron recordings is to analyze each neuron's spike train independently. This typically involves constructing a plot of average neural activity correlated to a specific cognitive event. For instance, perievent histograms depict mean firing rate synchronized to (peri-) a behavioral stimulus (event); similarly, a 'place field' recorded for hippocampal neurons consists of the correlation of neural firing rate with the animals instantaneous location in its environment. Multiple neuron activity is then used to examine to overall average or range of responses for neurons in a given brain area. More complex analyses of multiple spike trains were first described by Gerstein and Perkel (1969) prior to development of many of the above multiple neuron recording techniques. These techniques concentrated on determining cross-correlations between neurons, and statistically extracting repeated patterns of activity across many neurons with a view toward determining the connections between neurons. Many later analyses derived from these earlier techniques.

3.1 Population Vectors

A popular type of analysis is a direct examination of ensemble firing rate patterns corresponding to specific motor movements or behavioral events. This analysis has been termed the 'population vector' and is potentially quite powerful, especially in terms of encoding directional and velocity parameters. Population vectors consist of a set of measurements of the mean firing rates for each neuron in the ensemble corresponding to discrete times when unique events, or stimuli occur. The utility of a population vector analysis depends on identifying discrete conditions or 'states' (such as tracking visual images, or degrees of rotation of a monkey forearm), which correspond to a unique set of mean firing rates across the ensemble for each state. As applied by Georgopoulos et al. (1986),

the mean firing of each neuron in an ensemble recorded in non-human primate motor cortex was computed in correlation to forearm movements. A set of population vectors was obtained which corresponded to specific angles of arm rotation, then successfully compared to new recordings to test the accuracy of the population vector which 'predicted' the forearm angle prior to movement.

3.2 Cross-correlations

Multiple neuron recordings can also be analyzed simply by looking for repeating patterns of firing across populations of recorded neurons. These patterns may consist of spatial combinations of two or more neurons within the ensemble, a temporal pattern within single neurons, a particular sequence of firing between several neurons, or combinations of spatial and temporal oscillations. Ensemble spike trains can therefore be scrutinized using cross-correlation techniques and the construction of cross-correlation histograms (CCHs; Gerstein and Perkel 1969) for this purpose. Detection of specific spatiotemporal firing patterns (i.e., correlations between neurons) may suggest ways in which those neurons may be connected, or may simply result from common 'driving' influences on several different cells. The discovery that hippocampal neurons 'replay' recent experiences during sleep (Skaggs and McNaughton 1996) relied on the observation that temporal offsets in CCHs between pairs of hippocampal place cells corresponded to the sequence in which those place cells were activated. During the waking state, the temporal offset reflected the sequential movement of an animal through different places in the environment. During the following sleep cycle, the hippocampal neural pairs were again active with the same temporal offsets, suggesting a memory of the exploring the environment. One drawback in cross-correlation studies, however, is that while it is appealing to use cross-correlations to map temporal connectivity and patterned firing between neurons within an ensemble, such procedures are not well suited to circumstances where nonstationary processes (i.e., behavior) are likely to alter temporal firing patterns while the data is being recorded (see Hampson and Deadwyler 1999). On the other hand, the demonstration that cross-correlations between hippocampal neurons were altered provided important confirmation of the perturbations in place cell firing and spatial navigation observed in transgenic mice with deficient NMDA-receptors on CA1 hippocampal neurons (McHugh et al. 1996).

3.3 Multivariate Analyses

More elaborate analyses of ensemble spike trains include multivariate statistical treatments such as linear discriminant analysis and principal components

analysis (Nicolelis 1999). The differences and advantages of these analyses compared to those cited above are many. For instance, multivariate analyses simultaneously take account of the activity of all neurons in the ensemble, compared to cross-correlations which operate on pairs of neurons. Multivariate analyses incorporate both spatial (i.e., relationship between neurons within the ensemble) and temporal (time before and after events) information in the analyses, unlike population vectors which incorporate the firing of all neurons, but within an 'instantaneous' average of ensemble activity at discrete points in time. Finally, instead of producing one measure of correlation with behavioral and cognitive events for a given neuron, the multivariate components derived independent sources of variance within and between neurons comprising an ensemble.

Multivariate analyses provide the greatest potential for detecting neural patterns that correlate with perceptual, behavioral or cognitive event. Recordings of inferior temporal cortex (Miller et al. 1993), revealed many different patterns of encoding, including stimulus-specific and task (i.e., memory)-specific neural patterns. Likewise, analysis of ensembles of neurons from hippocampal (Deadwyler and Hampson 1997), parahippocampal regions (Young et al. 1997), and orbitofrontal cortex (Schoenbaum and Eichenbaum 1995) have demonstrated a broad spectrum of encoding that encompasses. Stimulus representation, memory storage, and formation of decision appropriate to the behavioral task.

4. Applications

Perhaps the best example of the utility of multiple neuron recording and analysis described above is the control of a robotic arm cited earlier (Chapin et al. 1999). In the study, ensembles of motor cortex neurons were recorded while a rat pressed a lever to cause a robotic arm to deliver water. A search for patterns of ensemble firing corresponding to the behavioral response would have required a massive search algorithm and intensive computation (as originally described Gerstein and Perkel 1969). However, principal components analysis of the ensemble spike trains revealed a pattern of neural firing that closely correlated to (and preceded) the limb movements required to press the lever and move the arm. Detection of the ensemble firing pattern while the animal performed the task allowed a computer to control the robotic arm, eventually allowing the rat to obtain water on the basis of the multiple neuron activity, without the requisite limb movement. Hence the principal components analysis allowed derivation of the brain function (behavioral response) from multiple neuron recording.

Single and multiple neuron recording have been applied to many purposes. Examination of the firing characteristics of single neurons provides a means of

correlating the activity of each neuron with the behavioral or cognitive activity of the animal. Multiple neuron recording is used simply to increase the yield of single neuron experiments, or for a more in-depth approach to correlating brain activity with external events. Analyses of the connectivity between neurons provides a framework for modeling neural circuits. Finally, extracting patterns of neural activity correlating to specific behavioral responses can result in a more detailed understanding of the role of specific brain areas in the process of cognition.

Perception: History of the Concept

'Perception' means an awareness of something, whether one's own thoughts and feelings, one's social surroundings, a business opportunity, the way to solve a math problem, or the current spatial layout. The term's meaning is often narrowed to basic aspects of perception with the senses. This article examines the history of the concept of sensory perception in philosophy and psychology. Perception has been studied as a source of knowledge and as a mental phenomenon in its own right. Visual perception was the first cognitive ability to be investigated with the methods of mathematical science, by the ancient Greeks, and was a central topic for the new philosophy and science of the seventeenth century. Quantitative studies of sensation and perception spurred the growth of experimental psychology in the nineteenth century. The twentieth century saw new perceptual theories and new techniques for examining the role of brain processes. Full understanding of how conscious awareness occurs in perception remains a goal for further research.

1. Perception in Ancient and Medieval Philosophy and Science

Human beings (as other animals) rely on their senses for survival. Although everyone uses the senses, it is not obvious how they work. Initial questions concerned their basic operation and their role in gaining knowledge. In vision, does something go out from the eye to meet the object, or does the object send

something to the eye? What do the senses reveal? Do they inform the observer of the very nature of things or are they fundamentally illusory? Or is their function primarily pragmatic?

Aristotle, working in fourth-century (BCE) Athens, wrote the first general treatise on psychology, described as *logon peri tes psyches* and entitled in Latin translation *De anima*, 'on the soul.' He considered the soul to be the principle of life or vitality, including reproduction and growth, sensory perception and purposeful activity, and intellectual theorizing. He offered a general theory of how the senses work, whereby something travels through a medium to each sense organ: light and color through air in the case of sight, vibrations in the case of sound, odors for smell, and so on. He also held that all knowledge is based on the senses. For 'proper sensibles' such as light and color, he postulated that a sample of the quality is received by the sensory soul 'without the matter' of the object. His medieval interpreters described this as the reception of a 'similitude' of the quality, or a 'real quality.' Aristotle held that sensory qualities alone do not reveal the essences of things, which are perceived by a higher cognitive faculty, the intellect, from observing changes over time. He differed from his teacher Plato, who held that in vision something goes from the eye into the air, and who taught that sensory perception is illusory, true knowledge arising from intellectual perception independent of the senses.

In this period 'optics' was about vision, not merely the physics of light (Lindberg 1976). In second-century Alexandria, Ptolemy developed a geometrical theory of vision, an extramission theory stating that something goes from eye to object. He modeled the relation between eye and object by a visual pyramid composed of a sheath of rays, with the object serving as base and the apex residing inside the cornea of the eye. The eye senses the direction and length of each ray, thereby perceiving the location of each point in the field of view, and so gaining full knowledge of the shapes, sizes, and places of things.

For centuries no theorist could formulate a mathematically rigorous intromission theory, with causation proceeding from object to eye. If one believes (correctly) that light is scattered from each point of an ordinary object in all directions, a problem arises that extramissionists did not face. It must be explained how the eye senses only one point for each point on the object, despite the fact that each point on the cornea receives light rays from all points in the field of view. Ibn al-Haytham (1030), working in Fatimid Cairo, produced the first accepted solution. He argued that the eye receives only the unrefracted rays (those that meet the cornea at right angles), and hence that it receives a cross-section of the visual pyramid preserving point-for-point the order of the scene. He also elaborated the theory that an object's true size is perceived through an unnoticed judgment that combines the visual angle under which an object is seen

with the perceived distance to the object. This explanation guided psychological theories of size perception for nearly a millennium.

2. Perception in the Modern Age

The Scientific Revolution of the seventeenth century brought changes in perceptual theory. Kepler's discovery of the retinal image revealed the internal optics of the eye and so produced a new solution to Ibn al-Haytham's problem, though without altering the latter's geometrical analysis of size perception or his theory of it, which was further developed by Descartes and Berkeley (Hatfield and Epstein 1979). Descartes postulated physiological systems to produce distance perception directly through the ocular-muscle processes of accommodation and convergence, and Berkeley sought to replace the psychology of unnoticed judgments with associative processes. Aristotle's theory that samples of qualities are absorbed by the senses was challenged by the new physics, according to which qualities in objects must be reduced to particles having only size, shape, motion, and position (primary qualities). Secondary qualities in objects, such as color, were now to be equated with such particles and their effects on perceivers. Descartes argued that sensory perception does not reveal essences, which are perceived by the intellect independent of the senses. The empiricist Locke denied intellectual perception of that sort, and held that the new physical theories were hypotheses to be tested against sensory observation. Both Descartes and Locke considered experienced qualities such as color to be products of the human sensory system. Contrary to later interpreters (e.g., Burt 1927), they did not regard them as illusory; if a subjectively produced color sensation is regularly or lawfully caused by qualities in objects, it can be used objectively to sort and classify such objects.

Eighteenth-century European theories of knowledge grappled with the new scientific image of the material world. Berkeley and Hume argued that the new theories devolve into paradox, as when 'red' is said both to be an experienced quality and a way light is reflected by surfaces. They sought to avoid skeptical conclusions by reducing knowledge of objects to the merely phenomenal. Reid (see Yolton 1984) countered with a 'common sense' affirmation of the reality and knowability of material objects (and of a deity, whose knowability was a primary motivation for him). Kant argued that analysis of the basis of actual knowledge in mathematics and natural science reveals that human knowledge cannot extend beyond sensory experience, so that metaphysical knowledge of God, an immaterial human soul, and the material world as it is in itself is not possible. Hegel countered that Hume, Kant, and others were wrong to think of the world in itself as lying beyond the phenomenally available world. The

natures of things are open to human knowledge, but can be grasped only through concepts that develop in a historical process of dialectic (see *Knowledge Representation*).

3. The Nineteenth Century

The nineteenth century was a golden age of sensory physiology and psychology in Germany (Turner 1994). G. Fechner, wanting to measure states of the soul, took psychophysical measurements for pressure on the skin, weights lifted by hand, line lengths perceived by sight, and the pitches of tones. Precise, empirical theories of color and spatial perception were developed by H. Helmholtz and E. Hering. In color theory, Helmholtz postulated three types of light-sensitive elements in the eye, with peak sensitivities at different wavelengths. Hering posited opponent-process mechanisms yielding four primary colors, red, green, yellow, and blue, along with a neutral white-black pairing. In spatial perception, Helmholtz argued that all ability for spatial localization is derived from experience, whereas Hering argued that the visual system has innate mechanisms for localizing sensations.

Nearly all major theorists accepted the assumption that perception is based on nonspatial, punctiform sensations varying only in quality and intensity. This assumption was shared by British associationists (e.g., J. Mill and J. S. Mill), nativists (H. Lotze), and empirists (W. Wundt, Helmholtz). It was questioned by Hering and C. Stumpf in Germany and W. James in the US. Dewey (1896) promulgated a functionalist approach to sensory perception, in which mind functions to adapt organisms to their environments.

4. Twentieth Century Trends

The idea that perception is built up from punctiform sensations was challenged by the Gestalt psychologists. Rather than punctiform sensations or two-dimensional perspective images, the Gestaltists regarded experience of the phenomenally given, meaningful world in three dimensions as the fundamental perceptual state. The American psychologist Gibson (1966) challenged the traditional theory that sensory stimulation provides greatly impoverished information about distant objects. He argued that, in vision, if one grants that organisms move and integrate information over brief intervals of time, then the information available at the eyes specifies fully the spatial layout of the scene. The British psychologist D. Marr developed computational models on the theory that Gibson-like assumptions about objects and stimulation are engineered into sensory systems. I. Rock at Rutgers University espoused the constructivist theory that perception results from inferential processes

which combine impoverished sources of stimulation, an approach shared by many information processing and computer vision theorists. Some theorists preferred to view perception as sensory information processing rather than the production of conscious states. New techniques for neurophysiological recording in living animals and brain imaging in humans permitted study of neural activity in perception, though behavioral and phenomenal data guided this research. At the end of the twentieth century all these currents remained visible in perceptual theorizing (Palmer 1999).

Philosophical approaches early in the twentieth century drew inspiration from Hume's phenomenalism and James' 'neutral monism,' the latter attempting to avoid the mind-body problem by arguing that both the psychological and the physical are composed from neutral existents found in perception. This led to theories of 'sense data' that have (in vision) the phenomenal properties of two-dimensional perspective projections. Such theories were challenged by critical and representational realism, and their phenomenological claims faded as philosophers took account of the Gestaltists and Gibson (Crane 1992). Philosophical interest in perception shifted from the problem of knowledge (now allotted to the philosophies of the sciences and other cognitive practices) to perception as an instance of the mind-body problem. As the neural correlates of sensory perception became better known, there remained a theoretical gap between neural or informational accounts and the conscious states manifest in perceptual experience. It is not clear how changes in the electrochemical state of neurons in the back of the brain could be the experience of red, despite it being known which neurophysiological patterns yield an experience of red, and which yellow. Much has been learned about how the senses work, but the characteristic feature of perception, conscious awareness, remains unexplained.

Perception of Extrapersonal Space: Psychological and Neural Aspects

We take for granted our ability to know where things are and to navigate through the environment. The effortless way in which we can look at or reach for an object belies the complex computations that go into determining its location. The psychological and neural processes that underlie our spatial abilities have been extensively explored in humans and animals. In this article, selected psychological aspects of spatial perception will be reviewed, followed by a consideration of some cortical mechanisms of spatial perception and representation.

1. Psychological Aspects

1.1 Basic Processes

Spatial perception involves not one but many specific abilities. Within the visual domain these include locating points in space, determining the orientation of lines and objects, assessing location in depth, appreciating geometric relations between objects, and processing motion, including motion in depth. These spatial skills can be applied to imagined objects as well as to external stimuli, as in the classic experiments of Shepard and Cooper (1986) on mental rotation. These

experiments showed that observers take longer to determine whether two objects are identical when the degree of mental rotation needed to align them increases. Similar sets of basic processes contribute to spatial representation in the auditory and somatosensory domains.

1.2 Space is Represented in Multiple Frameworks

Our subjective experience strongly suggests that we have direct access to a single coherent and overarching representation of space. Whether we localize a stimulus by sight, smell, hearing, or touch, we can respond to it with equal ease and with any motor system at our command. This introspection is misleading. There is no evidence for the existence of a single, explicit, topographic representation of space suitable for incorporating every kind of sensory input and generating every kind of motor output. On the contrary, the evidence points to multiple representations of space, in a variety of coordinate frames, and linked to separate output systems designed to guide specific motor effectors.

The particular representation of space in use at any time depends on the task the subject is trying to perform. For example, if you were to draw out a route for a hiking trip on a map, the route would be in the coordinates of the map, the piece of paper. If you were then going to walk along that route, you would have to begin by locating your current position within that coordinate frame and constructing a representation of the route with respect to your starting point. The first, map-based representation is an example of an allocentric representation, in which locations are represented in reference frames extrinsic to the observer. Allocentric representations include those centered on an object of interest (object-centered) and those in environmental (room-centered or world-centered) coordinates. The second representation, the one in the coordinates of the hiker's current position, is an example of an egocentric representation, in which locations are represented relative to the observer. Egocentric representations include those in eye-centered, head-centered, hand-centered, and body-centered coordinates. Experimental work in humans indicates that multiple reference frames can be activated simultaneously (Carlson-Radvansky and Irwin 1994).

2. Neural Aspects

2.1 Impairments of Spatial Perception in Humans

Much of our knowledge about the neural basis of spatial perception comes from observations in patients with spatial deficits following brain damage. These

include a wide range of perceptual and motor deficits, such as poor localization of visual, auditory, or tactile stimuli; inability to determine visual or tactile line orientation; impaired performance on mazes; impairment on tests of mental spatial transformations; right—left confusion; poor drawing; impaired eye movements to points in space; misreaching; defective locomotion in space; and amnesia for routes and locations. As can be seen from this partial list, spatial behavior involves many kinds of skills and, not surprisingly, a number of brain regions have been implicated in spatial perception and performance. Broadly speaking, the parietal lobe is responsible for spatial perception and representation of immediate extrapersonal space, while temporal and parahippocampal cortices are more involved in topographic memory and navigation (see *Navigation in Virtual Space: Psychological and Neural Aspects*). The frontal lobe receives input from both parietal and temporal cortex and is responsible for generating actions.

An important point about deficits in spatial perception is that they are far more common after right hemisphere damage than left. While patients with left hemisphere damage may also exhibit spatial deficits, it is clear that the right hemisphere in humans has a superordinate role in spatial processing and behavior (Heilman et al. 1985). Two kinds of spatial deficits following brain damage are particularly illuminating. First, a common sensorimotor deficit following parietal lobe damage is difficulty in using visual information to guide arm movements, referred to as optic ataxia. Patients with optic ataxia have difficulty with everyday tasks that require accurate reaching under visual guidance, such as using a knife and fork. They both misdirect the hand and misorient it with respect to the object, and are most impaired when using the contralesional hand to reach for an object in the contralesional half of space (see *Vision for Action: Neural Mechanisms*).

A second, classic disorder of spatial perception in humans is the tendency to ignore one half of space, called hemispatial neglect (see *Neglect, Neural Basis of*). The most common form of neglect arises from damage to the right parietal lobe and is manifested as a failure to detect objects in the left half of space. Neglect is more than just a visual deficit, however. It can occur separately or jointly across many sensory modalities (Barbieri and De Renzi 1989). Moreover, neglect occurs with respect to many different spatial reference frames. A patient with right parietal lobe damage typically neglects objects on the left but left may be defined with respect to the body, or the line of sight, or with respect to an attended object. Further, this neglect is dynamic, changing from moment to moment with changes in body posture and task demands (Behrmann 2000). Neglect is apparent even in the purely conceptual realm of internal images. Patients exhibit neglect when asked to imagine a familiar scene, such as a city square, and describe the buildings in it. The

portion of space that is neglected changes when they are asked to imagine the scene from a different viewpoint (Bisiach and Luzzatti 1978). As this example illustrates, neglect can occur with respect to an internal image constructed by the individual. Patients with neglect show evidence of using multiple reference frames, just as intact individuals do.

2.2 Spatial Perception in Animals is Impaired by Parietal Cortex Lesions

The role of parietal cortex in spatial perception has been explicitly tested in animal studies. Monkeys with posterior parietal lobe lesions exhibit many of the same deficits seen in humans, including deficits in the appreciation of spatial relations between objects and impairments in eye movements and reaching. They perform normally on tests of object discrimination but are selectively impaired on a spatial task that requires them to judge which of two identical objects is closer to a visual landmark. In contrast, monkeys with temporal lobe lesions are unimpaired on the spatial task but fail to discriminate between or recognize objects (Ungerleider and Mishkin 1982). This double dissociation between the effects of lesions, in combination with the discovery of distinctive cortical inputs to the parietal and temporal lobes, led to the concept of the dorsal and ventral visual processing streams (see *Visual Systems: Dorsal and Ventral*).

Neurons in the dorsal stream encode the types of visual information necessary for spatial perception. Neurons in specific dorsal stream areas are selective for orientation, depth, direction and speed of motion, rotation, and many other stimulus qualities appropriate for perceiving spatial information. The dorsal visual processing stream leads to posterior parietal cortex, where many kinds of visual information converge, including information about stimulus shape. An equivalent set of somatosensory processing areas send tactile information to anterior parietal cortex. Visual and somatosensory signals converge on single neurons within the intraparietal sulcus, which divides anterior and posterior parietal cortex. Auditory signals have also been demonstrated to contribute to spatial processing in monkey parietal cortex.

2.3 Parietal Neurons Encode Spatial Information in Multiple Reference Frames

The standard approach for investigating the role of parietal neurons in spatial perception is to record electrical activity from individual neurons while the monkey performs a spatial task. Because brain tissue itself has no sensory receptors, fine microelectrodes can be introduced into the brain without disturbing the animal's performance. By recording neural responses during carefully designed tasks, neural activity

can be related directly to the sensory and representational processes that underlie spatial behavior. The general conclusion from these studies is that the function of parietal cortex is to transform spatial information from sensory coordinates into the motor coordinates that are necessary for the guidance of action (Stein 1992, Andersen et al. 1997, Colby and Goldberg 1999).

2.3.1 Head-centered spatial representation in the ventral intraparietal area (VIP). Area VIP is located in the floor of the intraparietal sulcus, where inputs from high-order visual and somatosensory cortex converge. In the visual domain, VIP neurons are characterized by direction and speed selectivity, and thus resemble neurons in other dorsal stream visual areas that process stimulus motion (see *Motion Perception: Psychological and Neural Aspects*). In the somatosensory domain, these same neurons respond to light touch on the head and face. The somatosensory and visual receptive fields of individual neurons exhibit strong spatial correspondence: they match in location, in size, and even in their preferred direction of motion. The existence of spatially matched receptive fields raises an interesting question: what happens when the eyes move away from primary position? If the visual receptive fields were simply retinotopic, they would have to move in space when the eyes do and so would no longer match the location of the somatosensory receptive field. Instead, for some VIP neurons, the visual receptive field moves to a new location on the retina when the eyes move away from the straightahead position. For example, a neuron that has a somatosensory receptive field near the mouth and responds best to a visual stimulus moving toward the mouth will continue to respond to that trajectory of motion regardless of where the monkey is looking (Colby et al. 1993). These neurons have head-centered receptive fields: they respond to stimulation of a certain portion of the skin surface and to the visual stimulus aligned with it, no matter what part of the retina is activated. Neurons in area VIP send projections to the region of premotor cortex (see Sect. 2.4.1) that generates head movements. Area VIP neurons thus contribute to the visual guidance of head movements and may play a special role in hand, eye, and mouth coordination. They operate in a head-centered reference frame in order to generate appropriate signals for a particular motor effector system, namely that which controls head movements.

2.3.2 Eye-centered spatial representation in the lateral intraparietal area (LIP). In contrast to area VIP, neurons in area LIP construct an eye-centered spatial representation. Individual neurons become active

when a salient event occurs at the location of the receptive field. This can be a sensory event, such as the onset of a visual or auditory stimulus, or a motor event, such as a saccade towards the receptive field, or even a cognitive event, such as the expectation that a stimulus is about to appear, or the memory that one has recently appeared. The level of response reflects the degree to which attention has been allocated to the site of the receptive field (Colby et al. 1995).

Again, as we saw for area VIP, the animal's ability to make eye movements raises an interesting question about spatial representation. Neural representations of space are maintained over time, and the brain must solve the problem of how to update these representations when a receptor surface moves. With each eye movement, every object in our surroundings activates a new set of retinal neurons. Despite this constant change, we perceive the world as stable. Area LIP neurons contribute to this perceptual stability by using information about the metrics of the eye movement to update their spatial representation of salient locations (Duhamel et al. 1992). For example, LIP neurons are activated when the monkey makes an eye movement that brings a previously illuminated screen location into their receptive field. These neurons respond to the memory trace of the earlier stimulus: no stimulus is ever physically present in the receptive field, either before or after the saccade. The proposed explanation for this surprising finding is that the memory trace of the stimulus is updated at the time of the saccade. Before the saccade, while the monkey is looking straight ahead, the onset of the stimulus activates a set of LIP neurons whose receptive fields encompass the stimulated screen location, and they continue to respond after the stimulus is extinguished, maintaining a memory trace of the stimulus. At the time of the saccade, a corollary discharge, or copy of the eye movement command, containing information about the metrics of the saccade, arrives in parietal cortex. This corollary discharge causes the active LIP neurons to transmit their signals to the new set of LIP neurons whose receptive fields will encompass the stimulated screen location after the saccade. The representation of the stimulated location is thus dynamically updated from the coordinates of the initial eye position to the coordinates of the final eye position.

The significance of this observation is in what it reveals about spatial representation in area LIP. It demonstrates that the representation is dynamic and is always centered on the current position of the fovea. Instead of creating a spatial representation that is in purely retinotopic (sensory) coordinates, tied exclusively to the specific neurons initially activated by the stimulus, area LIP constructs a representation in eye-centered (motor) coordinates. The distinction is a subtle one but critical for the ability to generate accurate spatial behavior. By representing visual

information in eye-centered coordinates, area LIP neurons tell the monkey not just where the stimulus was on the retina when it first appeared but also where it would be now if it were still visible. The result is that the monkey always has accurate spatial information with which to program an eye movement toward a real or remembered target. The transformation from sensory to motor coordinates puts the visual information in its most immediately useful form. Compared to a head-centered or world-centered representation, an eye-centered representation has the significant advantage that it is already in the coordinates of the effector system that will be used to acquire the target. Humans with unilateral parietal lobe damage fail on an eye movement task that requires an eye-centered representation of a remembered target position. This failure presumably reflects an impairment of the updating mechanism in parietal cortex.

In sum, posterior parietal cortex plays a critical role in spatial perception and representation (Colby and Goldberg 1999). Physiological studies in monkeys show that parietal neurons represent spatial locations relative to multiple reference frames, including those centered on the head and the eye. Individual neurons (in area VIP) combine spatial information across different sensory modalities, and specific spatial reference frames are constructed by combining sensory and motor signals (in area LIP). In accord with the physiology, human neuropsychological studies show that neglect can be expressed with respect to several different reference frames.

2.4 Frontal Lobe Mechanisms of Spatial Representation

The parietal lobe transforms sensory representations of attended objects into the motor coordinate frames most appropriate for action. They do not actually generate those actions. Dorsal stream outputs to frontal cortex provide the sensory basis, in the correct spatial framework, for producing specific motor outputs. The following sections describe specific spatial representations found in three regions of frontal cortex.

2.4.1 Neurons in premotor cortex have head-centered and hand-centered visual receptive fields. Two different forms of spatially organized visual responsiveness have been described in ventral premotor cortex. First, in subdivisions representing facial movements, neurons respond to visual stimuli at specific locations relative to the head, much like those described above in area VIP. These neurons have been characterized by recording activity while objects approach the monkey's head along various trajectories. The preferred trajectory is constant with respect to the head,

and is not affected by changes in eye position (Fogassi et al. 1996). This specific zone of premotor cortex receives inputs from area VIP, and uses the same form of spatial representation. In both cases, stimuli are represented in the motor coordinate frame that would be most useful for acquiring or avoiding stimuli near the face by means of a head movement.

A different kind of spatial representation has been observed in subdivisions of premotor cortex involved in generating arm movements. Here, neurons respond to visual stimuli presented in the vicinity of the hand. When the hand moves to a new location, the visual receptive field moves with it. Moreover, the visual receptive field remains fixed to the hand regardless of where the monkey is looking, suggesting the existence of a hand-centered representation (Graziano et al. 1994). A fascinating observation indicates that some neurons in this area are capable of even more abstract forms of representation. Rizzolatti and coworkers have described neurons in premotor cortex that are activated both when the monkey grasps an object, such as a raisin, and when the monkey observes the experimenter performing the same action (Gallese et al. 1996). These 'mirror' neurons encode not just the monkey's own motor actions but also the meaning of actions performed by others (see *Pre-motor Cortex*).

2.4.2 Object-centered spatial representation in the supplementary eye field (SEF). Actions are directed toward objects in the environment and toward specific locations on an object. Picking up your coffee cup requires that you locate both the cup in egocentric space and the handle in relation to the cup. The spatial reference frame that guides such movements is not limited to the egocentric representations described above. Evidence from the supplementary eye field (SEF) demonstrates that single neurons can encode movement direction relative to the object itself (Olson and Gettner 1995). The SEF is a division of premotor cortex with attentional and oculomotor functions. Neurons here fire before and during saccades. In monkeys trained to make eye movements to particular locations on an object, SEF neurons exhibit a unique form of spatial selectivity: they encode the direction of the impending eye movement as defined relative to an object-centered reference frame. For example, a given neuron may fire when the monkey looks toward the right end of a bar placed at any of several different locations on the screen, regardless of whether the eye movement itself is a rightward or leftward saccade. Moreover, the same neuron will fail to respond when the monkey makes a physically identical eye movement toward the left end of the bar stimulus. This striking result indicates that single neurons can make use of quite abstract spatial reference frames. Object-centered spatial infor-

mation could potentially guide arm movements as well as eye movements. Moreover, neuropsychological evidence indicates that an object-centered reference frame can be used to direct attention: some patients exhibit object-centered neglect after parietal lobe damage (Behrmann 2000). Parietal lobe lesions in monkeys likewise produce impairments on tasks that require an object-centered spatial representation.

In sum, behavioral and neuropsychological studies indicate that we make use of multiple spatial representations in the perception of extrapersonal space. Neurophysiological studies are beginning to uncover the neural mechanisms underlying the construction of these egocentric and allocentric spatial representations.

Perception: Philosophical Aspects

Perception has been of perennial interest in philosophy because it is the basis of our knowledge of the external world. Because perception is a transaction between the world and the perceiver or their mind, investigations of the nature of the world perceived, the perceiver or their mind, or the relation between the two are possible. The philosophy of perception has focused on the latter two issues; although the study of perception has led to important views about the nature of the world perceived—particularly the idealism of Bishop Berkeley (see below)—such views are rare. Philosophers have asked instead: What is the nature of the relation between the mind of the perceiver and the world perceived? and What is the nature of the perceptual states of that mind? Contemporary philosophy of perception continues to debate these traditional questions, although it places more emphasis on the nature of the perceiving mind. It also tends to focus on visual perception rather than on the other senses, assuming—controversially—that what is true of vision is likely to be true of other modes of perception. Philosophers have also investigated the justification of perceptual belief, but because this is a branch of traditional epistemology, it is not dealt with here. This article considers some of the specific questions that have been raised in the investigation of the two general questions above as well as some of the answers given to them.

1. The Perceiver–World Relation

1.1 Direct Realism, Indirect Realism, and Phenomenalism

As I look out of the window, I see objects, such as buildings, and I see their properties, such as the green

color of their roofs. Presumably, the objects and their properties continue to exist even when I am not looking at them. (I can also be said to see events, such as the passing of pedestrians along the sidewalk, and facts, such as that there is traffic on the street, but we will ignore these matters here.) It seems to me that my acquaintance with the objects I perceive is an intimate one. I have no sense that anything stands between me and the buildings I am looking at. I do not feel that I am looking at a representation of the buildings as I might if I were looking at a photograph of them, nor that I am receiving information about them that has to be decoded. I merely open my eyes, and there they are.

This common sense view of visual perception is called *direct realism*. Direct realism holds that the objects one perceives are the physical objects of the external world and that these objects are perceived directly, that is, without the aid of any intermediary object or representation. A question arises about the status of the properties of objects when they are unperceived. *Naïve direct realism* holds that all of an object's perceived properties persist when it is unperceived; *scientific direct realism* holds that only the properties countenanced by science—such as shape—persist when an object is unperceived (see Dancy 1981, Martin 1998). Object color, for example, is thought by some to be a mind-dependent property and does not, on this view, persist when an object is unperceived. Scientific direct realism holds, therefore, that color is not perceived directly.

Despite its apparent obviousness, philosophers have challenged direct realism. An important objection to the view is expressed by the *argument from illusion*. Suppose I am having a hallucination of Beaver Lake. What is the object of my experience? Since I am not perceiving a physical object, I must be experiencing some other kind of object, perhaps a mental object. Further, since the experience of hallucinating Beaver Lake is, we may suppose, identical to the experience of actually perceiving Beaver Lake, the object in each case must be identical. In all true perception, therefore, there must be some (mental) object that acts as an intermediary or representation in the perception of the external world. The view that one is directly aware of intermediaries has been expressed as the claim that there is a *given* in perception—a nonconceptual state that forms the basis for full-blooded perception which requires the possession of concepts by the perceiver.

Various strategies have been adopted to resist the argument from illusion. First, the *adverbial theory of perception* denies the inference from the fact of hallucination to the claim that there is a mental entity that is the object of that hallucination. Instead, the theory holds that when I hallucinate a red triangle, for example, I am 'experiencing redly and triangularly', where 'redly' and 'triangularly' qualify the manner of experiencing, and does not presuppose the existence of a mental object. Because no inner mental object has to be posited even in cases of hallucination, it is possible

to reclaim the common sense view that in true perception it is physical objects that are directly perceived.

A second strategy is to deny the claim that the experience of true perception is indistinguishable from that of hallucination. The *disjunctive conception of perceptual experience* (see Snowdon 1990) holds that these experiences are constituted by different mental states. Thus, even if hallucinatory experience involves a mental representation, true perception need not, and could be direct.

A third strategy is to treat perception as a special kind of belief (or inclination to believe) rather than a sensory state (Armstrong 1961). On this view, to see a red triangle is to believe that there is a red triangle before one's eyes. A hallucination of a red triangle is no more than a false belief and does not, therefore, call for the introduction of a mental representation any more than the false belief that the local hockey team will win the Stanley Cup requires a mental object to be the thing believed. Some support for this view derives from the phenomenon of *blindsight* (Weiskrantz 1986), a state in which subjects with particular forms of brain damage are able to make crude perceptual judgements about the properties of stimuli in the absence of any conscious experience. If one is willing to accept the claim that blindsighted subjects are perceiving, then blindsight undermines the common sense view that all perception involves conscious experience. Since the perception-as-belief view does not make conscious experience central to perception, it is thus strengthened.

A fourth strategy for resisting the argument from illusion has been developed by information-theoretic approaches to perception which explicate the transaction between the world and the perceiver as an exchange of information (see Dretske 1981). For example, the *computational approach* to vision (Marr 1982) investigates how the information about properties of the environment contained in patterns of retinal stimulation can be extracted by the visual system.

Whatever the success of these strategies, direct realism also has trouble accounting for a different problem—that of perceptual error. If one's experience of the external world is mediated by a mental representation, then error can be explained as a mismatch between the representation and what it represents. But if there is no such representation but only a direct perception of the physical objects themselves, how is misperception possible?

These arguments support *indirect* or *representative realism* according to which external physical objects are perceived, but only indirectly, by means of the direct perception of intermediary entities (see Dancy 1981, Jackson 1977). These intermediaries are usually thought to be mental representations and have traditionally been called *ideas*, *appearances*, *sensibilia*, and *sensa*, among others. In the twentieth century they

have been referred to, rather notoriously, as *sense-data*. Much of the investigation into the nature of the relation between the perceiver and the world has focussed on two distinct questions: first, whether perception is in fact mediated in this way; and, second, whether one is consciously aware of the intermediaries. This investigation has been made more difficult by the fact that these quite different questions have often been conflated (Crane 1992).

Indirect realism also faces important objections, however; in particular, that it seems to lead to scepticism about the external world. If I am aware only of mental representations, then for all I know there is no external world at all. One response to this objection is to claim that it misconstrues the claims of indirect realism. The theory does not say that we have no access to external objects but rather that our access is by way of mental intermediaries. A second response embraces the sceptical possibility. Bishop Berkeley (1685–1753) famously argued that there is no external world but only perceptions, or, at any rate, that the external world is no more than collections of actual or possible perceptions, a view known as *phenomenalism* or *idealism*. Despite the importance of Berkeley's arguments for the theory of perception, however, the radical nature of his claims about the world have prevented them from being widely held.

Most philosophers of the first half of the twentieth century were indirect realists of the sense-datum variety. The early part of the second half of the twentieth century saw a complete rejection of sense-datum theory and indirect realism, and many contemporary philosophers are direct realists. Nevertheless, the tendency to think that there is some aspect of experience that involves a perceptual intermediary or that there are features of perceptual experience that cannot be construed as the direct perception of the external world has proved very strong. Some aspects of sense-datum theory have emerged again in the debate about qualia (see below), and even outright sense-datum theories are no longer anathema.

1.2 The Causal Theory

The *causal theory of perception* takes up a second important issue in the study of the relation between perceiver and world. The causal theory holds that the transaction between the perceiver and the world should be analyzed primarily in terms of the causal relation underlying that transaction (Grice 1961). One version of the causal theory claims that a perceiver sees an object only if the object is a cause of the perceiver's seeing it. Traditionally, indirect realism was associated with the causal theory, but not all recent versions of the causal theory are indirect theories (see Vision 1997). Indeed, the causal principle seems relevant to any view of perception, whether direct or indirect. This is illustrated by the case of a desert traveler who hallucinates an oasis. His eyes are closed, so nothing

outside of his own mind is causing the experience. However, it happens that an oasis is in fact in front of him, and, coincidentally, the hallucination matches the oasis perfectly. Despite the match between the experience and the environment, however, the absence of a causal relation moves us to deny that the case is one of perception (Pears 1976).

It seems clear, nevertheless, that an object's being a cause of a perceptual state is not sufficient for perception. For example, the state of perceiving an object typically will be the effect of a long causal chain, but typically only one of the links in the chain will be the object perceived. Suppose that a cup is illuminated by a flashlight. The flashlight is a cause of the perceptual state just as the cup is, but it is not the object perceived, and it is hard to see how appeal to causation alone will capture this obvious fact (Pears 1976).

1.3 Color Perception and the Primary–Secondary Quality Distinction

A different question about the relation between the perceiver and the world is the question of how successful the process of perception is at informing the perceiver about her environment. This question has been explored primarily in the debate about color perception, the most actively investigated topic in the area since the mid-1980s. Although philosophical interest in the perception of color is as old as philosophy itself, the contemporary debate has been invigorated by significant developments in color science and the introduction of these developments into philosophy (see Byrne and Hilbert 1997).

The perception of color is related to the success of visual perception because there is some reason to doubt whether objects actually possess colors. If it could be shown that objects do in fact fail to have colors, then visual perception would be seen to be mistaken in its representation of objects as color-bearers. It is generally assumed that the only way in which colors could be properties of external objects would be if they were physical properties—properties countenanced by science. The epistemological question whether color vision is reliable, therefore, is often recast as the metaphysical question whether there is a scientific property that is sufficiently close to our conception of color to deserve the name. If there is no such property, then doubt is cast on the idea that color is indeed an ordinary property of objects, and this in turn raises doubt about the accuracy of vision quite generally.

Two facts suggest that colors are not physical. First, color does not appear in the basic scientific description of the world. Second, colors seem to be variable in a way that ordinary physical properties are not. For example, a yellow object against a red background will appear greenish, but the same object against a green

background will look reddish, a phenomenon known as *simultaneous contrast*. Because of these facts, some philosophers have concluded that color is a *secondary quality*, that is, a property the existence of which is dependent on a perceiving mind. Secondary qualities are contrasted with *primary qualities*, such as shape or mass the existence of which is not dependent on the perceiving mind.

The philosophical investigation of color has led to two opposing camps. *Color realists* accept as an obvious fact that colors are properties of external objects. The task is to identify the physical property that is identical to color and show that the variability of color, such as that due to simultaneous contrast, does not undermine the idea that colors are properties of external objects. *Color antirealists* take the variability of color to be central to its nature and infer that color, as we understand that concept, does not exist. They hold that while some of the physical properties of the environment cause viewers to have color experience, there is nothing in the environment that is correctly represented by those experiences.

A special sort of realism attempts to accommodate both camps. The *dispositional theory of color* (usually associated with John Locke (1632–1704)) acknowledges both the variability of color and its external reality. An object is navy blue, on this view, if it has the disposition—a real property of the object itself—to cause normal perceivers to have experiences of navy blue in standard conditions. Colors are identical to these dispositions and, therefore, are properties of external objects. Color is variable because objects have at least as many color dispositions, and therefore colors, as there are color experiences.

2. The Perceiving Mind

2.1 Qualia

The debates concerning the nature of the mental states involved in perception recapitulate some of those dealing with the mind-world relation. Closely related to the color debate is the question about the existence of *qualia* (singular: *quale*, pronounced kwä'lē). The term is sometimes used to refer to the properties of the external environment, such as object color, that are experienced in perception. It is also used in more philosophically radical ways to refer to the properties of experiences themselves that give experiences their 'felt' qualities. This radical understanding of qualia thus takes them to be mental entities. Think, for example, about orgasms. There is a distinct feel to the experience of an orgasm that is absent in the mere belief that one is having an orgasm. After all, others can also believe that you are experiencing an orgasm without experiencing its characteristic feel. There is, as it is sometimes put, something it is like having certain kinds of experience. According to some, this is because

these kinds of experience possess qualia and beliefs do not.

Because qualia in the radical sense are mental items, the qualia debate has focused in part on whether the existence of qualia shows that *physicalism*—the view that the only entities, properties, and relations that exist are those countenanced by the physical sciences—is inadequate. (Philosophers who believe that it does have come to be called qualia freaks.) A central argument here is the knowledge argument (Jackson 1982): Mary is born and raised in an entirely black and white room. She becomes a scientist and, we suppose, learns everything a complete science can teach about perception and the world perceived. She then emerges from her room and, seeing a tomato for the first time, learns something new, namely, what it is like to see something red; that is, she experiences a red quale. But if Mary knows everything that a complete science can teach about the world and the perception of it, then she has learnt something that lies outside of the realm of the scientific, and physicalism is false.

The existence of qualia has also been taken to show that the dominant theory of mental states, called *functionalism*, is false. Functionalism holds that mental states are to be analyzed solely in terms of their relations to other mental states, relevant sensory input, and the behavioral output to which they lead. How these states are embodied in an animal, or indeed in a computer, is taken to be irrelevant to the nature of the states. Being in pain, for example, is to be analyzed as the state that is typically caused by damage to one's body; that causes one to withdraw from the source of the damage; that is related to feelings of anger or regret; and so on. But now consider which is made possible by the existence of qualia *spectrum inversion*. Inverted perceivers have systematically different color experience from normal perceivers because the qualia associated with their perceptual experience is inverted: what normal perceivers call 'red' they see as the color normal perceivers call 'green'; what normal perceivers call 'yellow' they see as the color normal perceivers call 'blue'; and so on. Despite their differences from normal perceivers, however, spectrally inverted perceivers could never be identified. After all, inverted perceivers would learn the same language as normal perceivers: they would call grass 'green' and tomatoes 'red' even if their experience of these objects was different from that of normal perceivers. If there were inverted perceivers, therefore, nothing in their behavior would reveal that they were inverted. In particular, nothing about the functional relations among their mental states revealed in their behavior would distinguish inverted from normal perceivers. By hypothesis, however, their experience is different. This argument—the *argument from spectrum inversion*—seems to show, therefore, that there has to be more to perceptual states than their functional relations.

It has been argued, however, that the very idea of qualia as properties of experience is based on a

confusion between the properties experience represents the environment as having and the properties experience itself possesses (Harman 1990). When one introspects to examine these putative properties of experience, one finds only the properties of the objects one is experiencing and not the properties of experiences. However, the former are not mysterious in the least; they are just ordinary properties of the physical world.

2.2 Perceptual Content

The qualia debate has also provided a way of investigating the nature of the *representational content* of perceptual states (see Villanueva 1996). Philosophers have asked whether there is something more to perceptual experience than what is represented by that experience—its representational content (or, simply, ‘content’). The view that denies that there is anything more is sometimes called the *intentional theory of perception* (Harman 1990) (where ‘intentional’ refers to what a mental state is about). On the intentional view, once the objects and properties in the scene perceived are specified, the content of the perceptual state has been exhausted. The qualia freak denies the intentional theory. He believes that there is more to perceptual states than their content, namely, the felt qualities of perceptual experiences. Consider orgasms again. Whatever the representational content of that state—perhaps that a particular physiological process is occurring in one’s body—the felt quality of the experience does not seem to be exhausted by that content.

In the realm of visual experience, intuitions are less clear. Suppose I am standing on a road on which there are two trees of the same height, one of which is at a distance of 100 meters and the second of which is at a distance of 200 meters. While I might judge the two trees to be of the same height, it is also apparent to me that the nearer tree takes up more space in my visual field. Since experience cannot correctly represent the trees both as equal in size and as different in size, it has been suggested that there is an entity, the visual field itself, that is the bearer of the latter aspect of the experience: the trees are represented as being the same size but appear in the visual field to have different sizes. There are thus two orders of properties: those of the visual field and their sister properties in the external world. On this view, the properties of the visual field are not part of the representational content of the perceptual state (Peacocke 1983).

A related question about perceptual content is whether it is conceptual or nonconceptual. The mainstream position is that all perceptual content is conceptual; the perceiver must possess the concepts for the entities and properties perceptually represented by her. For example, the ability to see a dog as a dog requires that one possess the concept ‘dog.’ This

mainstream position evolved in part as a rejection of sense-datum theory and its commitment to a nonconceptual given in perception. Nevertheless, some of the considerations that led to sense-datum theory have emerged again as relevant, and it has been argued that some perceptual representation does not require the possession of concepts. One such consideration is the epistemological view that conceptual thought has to be grounded in something that is nonconceptual (see Sedivy 1996). A second consideration is that perceptual states seem to represent the environment in a much more fine-grained fashion than a perceiver has the concepts for. For example, it is sometimes thought that the colors we see are more varied and subtly different from each other than we have concepts for. A third consideration is the desire to link the conceptual nature of thought with the contents of the computational states posited by the computational theory of vision. The computational theory of vision describes some of the content of a visual state in terms of various mathematical concepts, but perceivers do not have to possess those concepts in order to see.

One way of fleshing out nonconceptual content is in informational terms. A second way of doing so is by means of *scenarios*. A scenario is a representation of the way the physical space around the perceiver is filled out. It is specified by identifying within a perceiver-relative frame of reference the locations of object surfaces and their visible properties. The scenario itself, rather than any mental representation, is part of the content of the perceptual state, and it captures how the world looks to the perceiver independently of the perceiver’s conceptual resources (Peacocke 1992).

A third question about perceptual content has focussed on the computational theory of vision, in particular as it has been presented by David Marr (1945–80). Theorists have asked whether the contents of computational states have to make essential reference to the external world or whether they can be fully specified in terms of the perceiver’s states alone. The former view is one (but not the only) version of *externalism*; the latter is a version of *internalism* or *individualism*. (In philosophical jargon, externalism is committed to *wide content* whereas individualism is committed only to *narrow content*.) Externalism and internalism are positions that have been important in recent philosophy of mind, and the debate about computational vision has been pursued largely as an instance of the wider debate about what cognitive theory says about mental content quite generally (Burge 1996).

2.3 Spatial Perception

The scenarios mentioned above in connection with perceptual content are essentially spatial and reflect a concern in the philosophy of perception about space.

The importance of this topic has been recognized since Immanuel Kant's (1724–1804) *Critique of Pure Reason* tied spatial perception to the concept of an objective world. One reason for thinking that spatial perception is necessary for objectivity is that the perception of space seems essential to the formation of a concept of something that persists over time. The notion of persistence, in turn, is necessary to form a concept of an external object and, thereby, an objective world. Imagine a space-less world constituted entirely of sound. In such a world it seems impossible to articulate the distinction between, for example, two different C# sounds occurring at different times and the very same occurrence of C# being heard, disappearing, and then reappearing. It is argued, therefore, that without the perception of space, it is impossible to distinguish between the occurrence of multiple fleeting objects of the same type and a single persistent object (Strawson 1959). And without a notion of persistence, it is impossible to develop a concept of an objective world. A closely related idea is that the perception of space—or possibly the ability to attend selectively to different parts of space—is required in order to entertain thoughts about particular physical objects.

A second issue regarding space perception is that of the concept of a surface and its role in ordinary language and theories of perception. Under typical conditions, I only see part of the surface of an object. Does this mean that I see only part of an object? Or do I see a whole object but only part of it directly? And does that imply that I see the whole object indirectly? Investigation of the nature of surfaces thus leads to a distinction between direct and indirect perception that is rather different from the traditional one and does not depend on a distinction between the physical and the mental (Stroll 1988). The philosophical investigation of surfaces is important also because the computational theory of vision is in large part about how visual perception computes the surface properties of objects.

A third issue has come to be known as *Molyneux's question* or *Molyneux's problem* (see Degenaar 1996). It was formulated by the Irish scientist William Molyneux (1656–98) and discussed by John Locke with whom Molyneux corresponded. In a letter to Locke on July 7, 1688, Molyneux formulates the question: 'A Man, being born blind, and having a Globe and a Cube, nigh of the same bigness, committed into his Hands, and being Told, which is Called the Globe, and which the Cube, so as easily to distinguish them by his Touch or Feeling; Then both being taken from Him, and Laid on a Table, let us suppose his Sight Restored to Him; Whether he Could, by his sight, and before he touch them, know which is the Globe and which the Cube?' This question was addressed by almost every major theorist of perception following Molyneux and has been of sufficient historical interest to have led Ernst Cassirer to claim that it was the focus of eighteenth century epistemology

and psychology as well as the stimulus for all of Berkeley's philosophy. Molyneux's question continues to receive some attention from philosophers as a way of exploring a number of issues including the relation between different perceptual modalities, especially sight and touch; the existence and nature of the concept of space; and whether or not certain perceptual abilities are learned or innate.

Finally, the question of whether some quasiperceptual representations have significant spatial properties has been examined in the debate about mental imagery, the quasivisual experiences of imagination (see Block 1981). Philosophers and psychologists have debated the claim that mental images are essentially spatial as against the view that they are no more than the language-like representations thought by some to constitute the mental representations underlying all of cognition. Because there is now evidence that mental images are produced by the same neural machinery that produces visual experience, further investigation into imagery may shed light on the nature of visual representations, and research into vision may produce a better understanding of imagery.

Perception without Awareness, Psychology of

Perception without awareness (or, synonymously, unconscious perception) denotes the fact that a stimulus exerts causal influence on mental processes or behavior without being phenomenally experienced.

Research into unconscious perception began early in the history of experimental psychology (Peirce and Jastrow 1884, Sidis 1898). It is related to other domains working on unconscious processes, such as implicit memory (see *Implicit Memory, Cognitive Psychology of*) or implicit learning (Reber 1993). From the very beginning, experimenters attempted to prove the mere existence of unconscious perception. Researchers had to set up experimental demonstrations of a stimulus's causal influence on mental processes without its concomitant phenomenal experience. More recently, theorists began to ask how perception without awareness works.

The proof of perception without awareness usually needs two critical tests: (a) an indirect test that assesses the impact of a stimulus on mental processes or behavior, and (b) a direct test that establishes the absence of phenomenal experience of the stimulus in question. There was rarely doubt about the dem-

onstration of causal influence of a stimulus, but there was—and still is—much skepticism about the proof of absence of phenomenal experience. Therefore, experimenters aimed at enhancing the validity of thresholds in order to ensure that perception was indeed subliminal. Alternatively, some researchers were looking for procedures that circumvented the problem of thresholds. Finally, there is now some evidence for unconscious perception from research in neuroscience.

1. Early Studies

Early studies attempted to show that people were able to guess at above chance level without subjectively perceiving the stimulus (see Adams 1957, for a review). Much of the classical research has been criticized for its lack of proper control conditions and of proper measurements of consciousness (e.g., Eriksen 1960, Holender 1986). Holender, for example, criticized experiments using dichotic listening tasks for their lack of evidence that processing of the stimuli was indeed unconscious. In dichotic listening tasks, participants hear different information in both ears. They are instructed to attend to the information in one ear. It has been shown that information in the unattended ear may exert some influence on ongoing processing without subjective awareness of this information. Of course, if participants turned their attention to the unattended ear, they would be able to identify the content. Holender concluded that one can not be sure that unattended stimuli are in fact unconscious. Therefore, he proposed that manipulations should not limit mental resources by distracting attention, but should limit the available data by rendering perception of stimuli impossible.

2. Perception Below Threshold

At the start of the twenty-first century, several masking techniques are used to render the material—most of them visual stimuli—undetectable or unidentifiable. For example, to measure individual thresholds of detection, masked stimuli are presented on half of the trials. On the other half of the trials, only the mask is shown. Participants have to decide whether a stimulus is present or absent. If accuracy does not exceed chance level (mostly at 50 percent), absence of direct phenomenal experience is assumed.

In a well-known study, Marcel (1983) presented masked words below the subjective threshold of detection. Then he presented two words, one similar and one dissimilar to the masked word, in respect to either graphemic information or semantic content. Participants had to decide which word was similar to the masked word, either graphemically or semantically. They were able to make above-chance

guesses for each kind of judgment. As presentation time was decreased, judgments about graphemic similarity dropped to chance level first, followed by judgments about semantic similarity.

The logic underlying this kind of study is to show a significant effect in an indirect perceptual task (e.g., semantic discrimination) when there is a null effect in a direct task (e.g., detection). However, null sensitivity in direct tasks has always been a matter of controversy. If the criteria for null sensitivity in the direct test are too lenient, one may erroneously claim to have demonstrated unconscious perception. Conversely, if these criteria are too strong, it may be virtually impossible to demonstrate perception without awareness.

Therefore, some scholars have tried to circumvent the issue of thresholds and their measurements and taken different routes to demonstrate unconscious perception.

3. Alternative Approaches to Demonstrate Unconscious Perception

Reingold and Merikle (1988) designed an experimental setup that allows measuring unconscious perception without assessment of thresholds. Specifically, they proposed to use identical materials and experimental conditions for direct and indirect tests. The only difference between the two tests lies in the instruction: Conscious perception of stimuli is assessed in a direct test. In contrast, a task without reference to phenomenal experience of the stimulus is given in an indirect test. Normally, one would expect that performance in the direct test would show greater sensitivity than performance in the indirect task because conscious perception optimizes extraction and use of stimulus information. If the indirect measure shows greater sensitivity than the direct measure, however, one may conclude that unconscious processes mediate task performance. This was the case in a study on implicit memory effects by Kunst-Wilson and Zajonc (1980). Participants were exposed to random shapes for 1 ms during a learning session. At test, participants were shown 10 pairs of octagons, one old and one new. They had to decide either which of the two octagons has been shown before (direct test) or which of the octagons they liked better (indirect test). In the direct test, participants scored 48 percent, which was at chance level, but they preferred the old octagon in 60 percent of the cases, indicating greater sensitivity of the indirect than of the direct test. In studies on unconscious perception, however, it proved difficult to find the proposed indirect-greater-than-direct effect pattern.

More recently, Greenwald and his colleagues proposed to use performance in a direct test as independent variable and performance in an indirect test as dependent variable in a linear regression analysis

(Greenwald et al. 1995). These authors used a semantic priming paradigm as indirect test to show semantic activation without conscious perceptibility of the prime. It seems plausible that better performance in the direct test results in higher accuracy in the indirect test, yielding a linear regression function with positive slope. $X = 0$ denotes the point where conscious perception is completely absent. If there existed no effect of unconscious perception, the regression line would cross the zero point: $Y = 0$ if $X = 0$. If, however, there were an effect of unconscious perception even under complete absence of conscious identification, the intercept would be positive: $Y > 0$ if $X = 0$. In several experiments employing this kind of analysis, Greenwald and his colleagues (Draine and Greenwald 1998, Greenwald et al. 1995, 1996) were able to show reliable indirect effects under absence of direct effects.

4. Evidence from the Neurosciences

Other evidence of perception without awareness comes from patients with damage to the visual cortex. They typically do not see anything in the hemifield of vision that is opposite to the side of the damage (e.g., Pöppel et al. 1973, Weiskrantz et al. 1974). However, some of these patients are able to make visual discriminations in the blind hemifield although they reportedly do not have any phenomenal experience of the stimuli. This phenomenon is called 'blindsight.' Some authors suggested that blindsight may be caused by small islands of intact tissue in the primary visual cortex (Fendrich et al. 1992). Although correct visual discriminations may be caused by small, intact islands of accurate vision, this hypothesis cannot account for all phenomena observed in both monkeys and human patients (see Weiskrantz 1995).

Brain imaging techniques led to new indirect measures. Using an unconscious priming paradigm, Dehaene et al. (1998) have shown that masked primes influenced subsequent processing, accompanied by measurable modifications of electrical brain activity and cerebral blood flow.

We have discussed studies aimed at demonstrating that unconscious perception exists. We now turn to the question of how unconscious perception works.

5. Differences Between Conscious and Unconscious Perceptual Processes

One may think that unconscious perception is the same as conscious perception, except for the lack of phenomenal experience. In this view, unconscious perception is just a faint shadow of conscious perception. This view has been questioned, and there is good evidence that unconscious perception is driven by a limited-capacity system, unconscious perception

by a system that has much more capacity and allows the use of information from multiple sources (see MacLeod 1998). The main evidence comes from demonstrations of qualitative dissociations between conscious and unconscious perception. This means that conscious perception affects a variable in one direction, unconscious perception in the opposite way, suggesting different underlying mechanisms (see Merikle and Daneman 1998). An elegant study showing such a dissociation has been reported by Jacoby and Whitehouse (1989). In a recognition test, a target word was presented and participants had to decide whether or not it had appeared in a list presented before. Shortly before the target, a prime was shown that was either identical to or different from the target. If the primes were shown subliminally, identical primes resulted in more 'old' responses than different primes. If the primes were shown supraliminally, however, identical primes resulted in less 'old' responses than different primes. This qualitative dissociation suggests that participants who saw supraliminal primes were able to correct their judgments for the supposed influence of the primes. If exposed to subliminal primes, however, participants were unable to avoid the impact of the prime and were biased toward 'old' responses when prime and target were identical. Several other studies yielded similar dissociations (e.g., Debner and Jacoby 1994, Marcel 1980, Merikle and Joordens 1997), suggesting that conscious and unconscious perception are governed by different mechanisms.

6. Outlook

There is fair evidence that unconscious perception exists. However, there is no evidence that effects of unconscious perception, caused by exposure to subliminal messages, are of any practical relevance (Greenwald et al. 1991, Vokey and Read 1985).

Beyond the proof of existence, interesting questions about unconscious perception remain open. One question pertains to the durability of unconscious perception (see Merikle and Daneman 1998). It has been shown that implicit memory effects may last for several days (see *Implicit Memory, Cognitive Psychology of*). In contrast, most studies on unconscious perception dealt with effects that lasted a few seconds. In implicit memory tasks, encoding is conscious, but retrieval is assumed to be unconscious. In perception without awareness, encoding is unconscious. Do long-term effects exist only if encoding is conscious, or is it possible to find long-term effects of unconscious encoding? Poetzl ([1917] 1960) has shown that briefly presented materials may be manifest in dreams during the following night although people were unable to remember the materials after the initial presentation. The Poetzl phenomenon, together with more recent findings on memory for information encoded during anesthesia (see Merikle and Daneman 1996 for a meta-

analysis) suggest that unconscious influences may last for hours.

As discussed above, another major question is how perception without awareness works. This research has only recently begun and will intensify, stimulated by recently developed methods in the neurosciences and cognitive psychology (e.g., the process dissociation procedure, see Debner and Jacoby 1994) that open up opportunities for research into neural correlates and cognitive mechanisms of unconscious perception.

Brain imaging methods may bring new opportunities to look into neural pathways related to unconscious perception. Specifically, these methods may bring new insights into qualitative dissociations between neural substrates connected to conscious perception and neural substrates connected to unconscious perception, as demonstrated in a study by Morris et al. (1998). These authors paired an angry face with (uncomfortable) white noise. Subliminal presentation of the conditioned angry face resulted in increased neural activity in the right, but not left amygdala. In contrast, supraliminal presentation of the same face resulted in increased neural activity in the left, but not right amygdala. Moreover, it has been shown that simple stimulus features may proceed to the amygdala and trigger an emotion without involvement of cortical structures (see LeDoux 1995). Although any conclusion about presence or absence of awareness in perceiving such features is premature, it enables theorists to conceive ways of how information may influence mental processes without reaching consciousness.

R. Reber and W. Perrig

Perceptrons

Perceptrons was the generic name given by the psychologist Frank Rosenblatt to a family of theoretical and experimental artificial neural net models which he proposed in the period 1957–1962. Rosenblatt's work created much excitement, controversy, and interest in neural net models for pattern classification in that period and led to important models abstracted from his work in later years. Currently the names (single-layer) Perceptron and Multilayer Perceptron are used to refer to specific artificial neural network structures based on Rosenblatt's perceptrons. This article references the intellectual context preceding Rosenblatt's work and summarizes the basic operations of a simple version of Rosenblatt's perceptrons. It also comments briefly on the developments in this topic since Rosenblatt.

Rosenblatt's first (partial) report in January 1957 was titled *The Perceptron: A Perceiving and Recognizing Automaton*. A subsequent report, in January 1958, titled *The Perceptron: A Theory of Statistical Separability in Cognitive Systems* was adapted for publication (Rosenblatt 1958). A compendium of research on perceptrons by Rosenblatt and his group is *Principles of Neurodynamics* (Rosenblatt 1962).

Rosenblatt's research was done in the context of: the neobehaviorism of Hull (1952), the general principles of neuromodeling of behavior proposed by Hebb (1949), the Threshold Logic Unit (TLU) neuron model of McCulloch and Pitts (1943), proposals for brain modeling based on neurophysiology (Eccles 1953) and symbolic logic, switching theory and digital computers (Shannon and McCarthy 1956), the stimJEUlus sampling models of Estes and Burke (1953), the linear operator probabilistic learning models of Bush and Mosteller (1955), and statistical classification procedures (e.g., Rao 1955).

The basic building block of a perceptron is an element that accepts a number of inputs x_i , $i = 1 \dots N$, and computes a weighted sum of these inputs where, for each input, its fixed weights β can be only $+1$ or -1 . The sum is then compared with a threshold θ , and an output y is produced that is either 0 or 1, depending on whether or not the sum exceeds the threshold. Thus

$$y = \begin{cases} 1 & \text{if } \left(\sum_{i=1}^N \beta_i x_i \right) \geq \theta \\ 0 & \text{if } \left(\sum_{i=1}^N \beta_i x_i \right) < \theta \end{cases}$$

A perceptron is a signal transmission network consisting of sensory units (S units), association units (A units), and output or response units (R units). The 'retina' of the perceptron is an array of sensory elements (photocells). An S-unit produces a binary

Figure 1
The mark 1 perceptron

output depending on whether or not it is excited. A randomly selected set of retinal cells is connected to the next level of the network, the A units. As originally proposed there were extensive connections among the A units, the R units, and feedback between the R units and the A units. A simpler version omitting the lateral and feed-back connections is shown in Fig. 1 This simplification is the perceptron considered here.

Each A unit behaves like the basic building block discussed above, where the $+1$, -1 weights for the inputs to each A unit are assigned randomly. The threshold θ for all A units is the same. The binary output of the k^{th} A unit ($k = 1, \dots, m$) is multiplied by a weight a_k , and a sum of all m weighted outputs is formed in a summation unit that is the same as the basic building blocks with all weights equal to $+1$. Each weight a_k is allowed to be positive, zero, or negative, and may change independently of other weights. The output of this block is again binary, depending on a threshold, t , that is normally set at 0. The binary values of the output are used to distinguish two classes of patterns that may be presented to the retina of a perceptron. The design of this perceptron to distinguish between two given sets of patterns involves adjusting the weights a_k , $k = 1, \dots, m$, and setting the threshold θ .

Rosenblatt (1962) proposed a number of variations of the following procedure for 'training' perceptrons. The set of 'training' patterns, that is, patterns of known classification, are presented sequentially to the retina, with the complete set being repeated as often as needed. The output of the perceptron is monitored to determine whether a pattern is correctly classified. If not, the weights are adjusted according to the following 'error correction' procedure: If the n -th pattern was misclassified, the new value $a_k(n+1)$ for the k -th weight is set to

$$a_k(n+1) = a_k(n) + y_k(n) * \delta(n)$$

where $\delta(n)$ is 1 if the n -th pattern is from class 1 and $\delta(n)$ is -1 if the n -th pattern is from class 2. No adjustment to the weight is made if a pattern is classified correctly.

Rosenblatt conjectured that, when the pattern classes are 'linearly separable' the error correction 'learning' procedure will converge to a set of weights defining the separating hyperplane that correctly classifies all the patterns. The shortest proof of this perceptron convergence theorem was given by A. J. Novikoff. Subsequent contributions related the simple perceptron to statistical linear discriminant functions

and related the error-correction learning algorithm to gradient-descent procedures and to stochastic approximation methods that originally were developed for finding the zeros and extremes of unknown regression functions (e.g., Kanak 1962).

The simple perceptron described is a series-coupled perceptron with feed-forward connections only from S units to A units and A units to the single R unit. The weights a_k , the only adaptive elements in this network, are evaluated directly in terms of the output error.

Minsky and Papert (1969) further reduced the simple perceptron to a structure with sampled connections from the 'retina' directly to the adjustable weights. This reduced structure is referred to as a *single-layer perceptron*. There is no layer of 'hidden' elements, that is, additional adjustable elements for which the adjustment is only indirectly related to the output error. A feed-forward perceptron with one or more layers of hidden elements is termed a *multilayer perceptron*. Rosenblatt investigated *cross-coupled perceptrons* in which connections join units of the same type, and also investigated *multilayer back-coupled perceptrons*, which have feedback paths from units located near the output. For series-coupled perceptrons with multiple R units, Rosenblatt proposed a 'back-propagating error correction' procedure that used error from the R units to propagate correction back to the sensory end. But neither he nor others at that time were able to demonstrate a convergent procedure for training multilayer perceptrons.

Minsky and Papert (1969) proved various theorems about single-layer perceptrons, some of which indicated their limited pattern-classification and function approximating capabilities. For example, they proved that the single-layer perceptron could not implement the Exclusive OR logical function and several other such predicates. Later, many writing on Artificial Neural Networks (ANN) blamed this book for greatly dampening interest and leading to a demise of funding in the USA for research on ANN's. The section on 'Alternate Realities' in Kanak (1992) details why the blame is misplaced. As noted there, by 1962 (see, e.g., Kanak 1962) many researchers had moved on from perceptron type learning machines to statistical and syntactic procedures for pattern recognition.

Minsky and Papert's results did not apply to multilayer perceptrons. Research on ANN's, biologically motivated automata, and adaptive systems continued in the 1970s in Europe, Japan, the Soviet Union, and the USA, but without the frenzied excitement of previous years, which also came back starting in the early 1980s. In a 1974 Harvard University dissertation Paul Werbos presented a general convergent procedure for adaptively adjusting the weights of a differentiable nonlinear system so as to learn a functional relationship between the inputs and outputs of the system. The procedure calculates the derivatives of some function of the outputs, with respect to all inputs and weights or parameters of the

system, working backwards from outputs to inputs. However, this work, published later in a book by Werbos (1994), went essentially unnoticed, until a few years after Rumelhart et al. (1986), independently popularized a special case of the general method. This algorithm, known as error backpropagation or just backpropagation, adaptively adjusts the weights to perform correct pattern classification using gradient descent and training samples. It propagates derivatives from the output layer through each intermediate layer of the multilayer perceptron network. The resurgence of work on multilayer perceptrons and their applications in the decades of the 1980s and 1990s is directly attributable to this convergent backpropagation algorithm.

It has been shown that multilayer feedforward networks with a sufficient number of intermediate or 'hidden' units between the input and output units have a 'universal approximation' property: they can approximate 'virtually any function of interest to any desired degree of accuracy' (Hornik et al. 1989). Several modifications of the basic perceptron learning procedure that make perceptron learning well behaved with inseparable training data, even when the training data are noisy and not error free, have been proposed in recent years and various ANN learning procedures have been shown to related to known statistical techniques. The reference list includes some recent books with tutorial material covering Perceptrons and related ANN's.

Perceptual Constancy: Direct versus Constructivist Theories

Fortunately, our perception of the environment surrounding us is usually quite veridical, accurate, and stable. While laypersons take this ability of ours for granted, students of perception have pointed out that it is actually quite a feat, since the stimulation reaching our senses changes continuously. If we take the visual perception of size as an example, we find that the size of the retinal image of, say, another person changes with that person's distance from us. In spite of these changes we perceive that person as being of constant size and not shrinking or expanding with changes in distance. This 'feat' of perception has aroused a great deal of interest and theories have been proposed to account for it. Prominent among these are two contrasting views of how it is achieved. One view, the 'constructivist,' maintains that the perceptual system is 'intelligent.' In order to attain veridical perception it utilizes high-level mental processes to correct for the changes in stimulation reaching our senses. In contrast, the 'direct' approach claims that there is no need to posit such mental processes to explain veridical

perception, maintaining that the sensory information reaching our senses suffices to explain perceptual veridicality and that what is needed is a much deeper analysis of that sensory information.

1. Stability and Constancy in Perception

The ability of our perceptual system to overcome the effects of changes in stimulation and maintain a veridical and stable percept is called *perceptual constancy* (Epstein 1977, Walsh and Kulikowski 1998). In discussing the constancies it is common to make a distinction between the *distal* stimulus and *proximal* stimulus. The distal stimulus is the actual physical stimulus, the physically objective dimensions of the viewed object. The proximal stimulus, in the case of vision, is the very image that falls on the retina. It changes with changes in position or lighting of the physical stimulus. Constancy can be defined as the ability to correctly perceive the distal stimulus; that is, the stable properties of objects and scenes, in spite of changes in the proximal stimulus.

One example of constancy is *shape constancy*, which refers to the ability of the visual system to ascertain the true shape of an object even when it is not viewed face on but slanted with respect to the observer. In an example of shape constancy the distal stimulus might be a door half open, while the proximal stimulus will be the trapezoid shape it projects on the retinas. Shape constancy in this case would be the perception of the distal rectangular shape of the door in spite of the fact that the proximal shape is far from rectangular. Another example of constancy is *lightness constancy*. Lightness refers to the perceived reflectance of an object; high reflectance is perceived as white and very low reflectance as black, with intermediate reflectances as various shades of gray. We are capable of perceiving the distal lightness of a surface in spite of the fact that the proximal amount of light reaching our eyes changes with changes in the amount of light illuminating that surface. For example, if we hold a piece of chalk in one hand and a piece of charcoal in the other, the chalk will be perceived as white and the charcoal as black. This will be true if we observe the two in a dimly lit room or in bright sunshine, in spite of the fact that the amount of light reaching the eyes from the charcoal in the sunshine might be greater than that from the chalk in the dim room lighting.

The perceptual constancy that has received the greatest amount of research attention is *size constancy* (Ross and Plug 1998). If the distance is not very great we usually perceive the distal size of objects in spite of the changes in their proximal size as their distance from us changes. The two theoretical approaches mentioned above, the constructivist and the direct, deal with size constancy differently. According to the constructivists, size constancy is achieved through some process whereby the perceptual system perceives the object's distance and then takes the distance

into account and 'corrects' the proximal image to yield a true distal percept. The direct approach asserts that there is no need to involve the perception of distance in the perception of size. Instead, it claims that enough information exists in the visual environment to allow direct perception of size without the need for aid from additional 'higher' mental processes.

2. Two Theoretical Approaches to Perception

The two approaches, the constructivist and the direct, differ in many respects, but the main differences between them revolve around two interrelated issues, the richness of the stimulation reaching our sensory apparatus, and the involvement of 'higher' mental processes in the apprehension of our environment. The constructivists see the stimulation reaching our senses as inherently insufficient for veridical perception, necessitating an 'intelligent' mechanism that utilizes inferential processes to supplement the information available to the senses and resolve its inherent ambiguity. The direct theorists, in contrast, argue that the information in the environment is sufficiently rich to afford veridical perception with no need for sophisticated algorithms. The constructivists see perception as multistage with mediational processes intervening between stimulation and percept; i.e., perception is indirect. The direct theorists see perception as a single-stage process; i.e., it is direct and immediate. For the constructivists, memory and schemata based on past experience play an important role in perception. The direct approach sees no role for memory in perception. Finally, the two approaches differ in the aspects of perception they emphasize: the constructivists excel at analyzing the processes and mechanisms underlying perception, whereas the direct approach excels at the analysis of the stimulation reaching the observer.

2.1 The Constructivist Approach

This approach has also been called Helmholtzian, indirect, cognitive, algorithmic, and mediational, among other labels. It is the older of the two, ascribing some of its roots to Helmholtz's (1867) notion of 'unconscious inference,' which maintains that veridical perception is achieved by an inference-like process which transpires unconsciously. A somewhat similar approach was adopted and elaborated more recently by Rock (1983) in his *The Logic of Perception*. This book contains the most detailed account of the constructivist view and the evidence in its favor. The first sentence in the book is, 'The thesis of this book is that perception is intelligent in that it is based on operations similar to those that characterize thought.' (Rock 1983, p.1). Rock makes it clear that this thought-like process occurs unconsciously. He also writes, '... a summary statement of the kind of theory I propose

to advance in the remainder of the book. My view follows Helmholtz's (1867) that perceptual processing is guided by the effort or search to interpret the proximal stimulus, i.e., the stimulus impinging on the sense organ, in terms of what object or event in the world it represents, what others have referred to as the "effort after meaning".' (Rock 1983, p. 16). In other words, Rock is conceiving of perception as an effortful, but unconscious, attempt at identifying an object or event.

In his discussion of size perception, Rock specifically invokes a syllogistic inferential mechanism: 'I will argue that the process of achieving constancy is one of deductive inference where the relevant "premises" are immediately known. That is to say, in the case of a specific constancy such as that of size, two aspects of the proximal stimulus are most relevant, one being the visual angle subtended by the object and the other being information about the object's distance.' (Rock 1983, p. 240). Rock sees size perception as depending on two perceptions, that of proximal size and that of distance, together leading through a syllogism to the veridical distal percept. Like other constructivists, this approach posits some sort of combination of proximal size information and distance information in the achievement of size constancy. In a similar manner, the same combinatorial process holds for all the constancies, according to the constructivist view.

The equation of perceptual and thought processes is difficult to verify empirically, but there are implications from this approach that are verifiable. As can be seen above, the constructivist approach implies that at least two perceptions are involved in perceiving size, that of the proximal size of the object and that of its distance. In a later book, *Indirect Perception*, Rock (1997) collected a large group of studies showing 'that perception is based on prior perception, implying a perception-perception chain of causality.' This interdependence of perceptual processes is something that can be examined empirically and, indeed, the studies reprinted in that book clearly evidence that chain of causality. However, it should also be noted that all of these studies utilize somewhat artificial situations where a manipulation is used in order to create some sort of illusory perception or misperception. A simple example is studies where subjects are presented with monocular views of the stimuli causing misperception of the three-dimensional spatial arrangement. Here, for example, misperceived distance is accompanied by the misperception of other perceptual qualities.

2.2 The Direct Approach

This approach is also referred to as ecological, Gibsonian, sensory, and immediate, among other labels. It is in the main an approach developed by James J. Gibson who expounded it in his *The Ecological Approach to Visual Perception* (Gibson

1979). In that book, Gibson proffered an exciting new approach to the study of visual perception that included many new concepts and new ways of looking at perception. The entire first half of the book is devoted to a novel analysis of the ambient, or surrounding, environment and the information it provides the observer. Gibson finds the classical approach of describing the stimuli for perception in terms of stimulus energies impinging upon the receptors completely unsatisfactory. He points to the differences between these energies and the optical information available in the ambient optic array. That information is *picked up* by a stationary or moving observer. Perception consists of perceiving events, i.e., perceiving changes over time and space in the optic array.

What sort of information is picked up in direct perception? Gibson suggests that there exist invariants in the optic array that serve to supply the observer with unequivocal information. These invariant aspects of the information remain constant in spite of changes in the observer's viewpoint. He musters a great deal of evidence to prove this point. Among the items of evidence he presents is a study of size perception of his where observers were asked to match the height of stakes planted at various distances in a very large plowed field with a set of stakes of varying size nearby. His finding was that size perception remained veridical no matter how far away the stake was planted. Unlike the constructivists, Gibson does not ascribe this size constancy to the taking into account of distance, but rather to the pickup of invariant ratios in the ambient optical array surrounding the observer. In the case of perception of size, he proposes two such invariant ratios. One is the amount of surface texture intercepted by the object's base as it sits on that surface. The second is the horizon ratio, the ratio between the object's height and its distance from the horizon, both measured in the two-dimensional projection of the optic array. There is no need, according to his view, for perceived distance to be involved here, or for the inferential mental processes that the constructivists purport to underlie size perception.

One of Gibson's most important contributions is the concept of *affordances*. He writes, 'The *affordances* of the environment are what it *offers* the animal, what it *provides* or *furnishes*, either for good or for ill' (Gibson 1979, p. 127). In other words, affordances refer to the possible actions that can be taken by the perceiver vis-à-vis objects in the environment. Thus, for example, some surfaces in the environment are 'stand-on-able,' or 'climb-on-able,' or 'sit-on-able.' 'The psychologists assume that objects are *composed* of their qualities. But I now suggest that what we perceive when we look at objects are their affordances, not their qualities.' (Gibson 1979, p. 134), and, '... the basic affordances of the environment are perceivable and usually perceivable directly, without an excessive amount of learning.' (Gibson 1979, p. 143). Gibson is

suggesting that the direct perception of, say, a chair does not constitute recognizing it as a type of furniture labeled 'chair,' i.e., categorizing it, but rather the perception of the chair's affordance, i.e., that it contains a surface that is sit-on-able.

As may be clear from the foregoing description, Gibson's conception is one of an active perceiver exploring his environment. Eye, head, and body movements are part and parcel of the perceptual process. Perception transpires continuously over both time and space. 'Space' here refers not to an empty space but to the many surfaces that make up the environment, the most important being the terrain that at times reaches the horizon. The horizon is of importance as it serves as a useful reference standard, and when it is occluded Gibson speaks in terms of an implicit horizon, presumably similar to what architects and others have called the eye-level plane. With such a conception, Gibson is totally averse to the reductionist experimental paradigms used by the constructivists. Brief exposures or looks through monocular 'peep-holes' do not represent true perception, in his view.

In his book, Gibson almost totally refrains from discussing the processes underlying perception. Perception is simply the pickup of information from invariants in the ambient environment. His only allusions to underlying processes are in terms of resonance: 'In the case of the persisting thing, I suggest, the perceptual system simply extracts the invariants from the flowing array; it *resonates* to the invariant structure or is *attuned* to it. In the case of substantially distinct things, I venture, the perceptual system must *abstract* the invariants. The former process seems to be simpler than the latter, more nearly automatic' (Gibson 1979, p. 249).

3. *Summing Up and a Possible Reconciliation*

The two theoretical approaches, the constructivist and the direct, obviously differ in many respects. The former endows the perceiver with 'higher' mental capacities that allow him/her to compensate for the purported insufficiency of the stimulation reaching the sensory apparatus. In contrast, the direct approach attempts to delineate the richness of information available in the ambient environment as picked up by an active perceiver, allowing direct perception without the need for additional mental processes. What is more, the proponents of each of these two approaches utilize research methods commensurate with the tenets of the respective approach. Thus, for example, constructivist researchers utilize impoverished or illusory stimulus conditions (e.g., brief and/or monocular presentations), calling for the intervention of 'higher' processes to compensate for the lack of adequate stimulus information. The adherents of the direct theory, on the other hand, utilize rich stimulus conditions without time limitations.

In spite of the seemingly irreconcilable differences between the two theoretical approaches, a means of bridging them does exist. They can co-exist within a broader theory of perception (Norman 2001). This broader theory is based on the accumulating neurophysiological, neuropsychological, and psychophysical research findings that point to the existence of two distinct visual systems, the dorsal and the ventral (see, e.g., Milner and Goodale 1995). The central idea is that the direct approach broadly parallels the functions of the dorsal system, and the constructivist approach broadly parallels those of the ventral system. These two visual systems are found in different parts of the brain, the dorsal mainly in the parietal lobe, the ventral mainly in the temporal lobe. The two deal with different aspects of perception. The dorsal system deals mainly with the utilization of visual information for the guidance of motor behavior in one's environment. The ventral system deals mainly with the utilization of visual information for 'knowing' one's environment, i.e., identifying and recognizing items previously encountered and storing new visual information for later encounters. However, it should be stressed that both systems process similar information for somewhat different purposes. Thus, for example, both systems are involved in the perception of size, albeit with somewhat different specializations. The dorsal system picks up size information for motor tasks, such as grasping an object. The ventral system utilizes size information for distinguishing between objects, say, between a real car and an accurate toy model.

Emerging from this attempt at integrating the two approaches into a single theory is a dual-process approach to visual perception. According to this approach, much of our day-to-day pickup of visual information is carried out by the dorsal-direct system without involving much awareness. In the main the information picked up is that which allows the organism to function within its environment, i.e., Gibson's affordances. The ventral-constructivist system, on the other hand, deals with the interface between the visual input and cognition, and we are normally aware of its output. Only it possesses a long-term memory and therefore any type of identification or recognition must transpire within it. As the dorsal system is mainly concerned with directing motor behavior in one's environment it must rely on body-centered information, in absolute units, about the environment and the objects in it. In contrast, the ventral system in its attempt to recognize objects can suffice with relative, object-centered, information. It is probably for this reason that the dorsal system yields more accurate information about the visual environment than does the ventral system. Thus, it is suggested that perceptual constancy is usually attained by the dorsal system. However, there are cases where the ventral system is also involved, as when the visual information is sparse or ambiguous, or when the

observer is required not only to act upon some aspect of the visual environment, but also to make a judgment about some object in that environment.

Perceptual Learning

1. Improvement of Perception Through Training

It has been known for a long time that visual recognition of objects improves through training. For beginners in the study of histology, all specimens, such as the liver, lung, or kidney, look quite similar. Sooner or later, however, the advanced student wonders how one could possibly miss the difference. This type of visual classification is a relatively complex visual task, but it has also been known for a long time that performance in much simpler perceptual tasks improves through practice, as for example in the cases of vernier discrimination (McKee and Westheimer 1978), stereoscopic depth perception (Ramachandran and Braddick 1973), and discrimination between line orientations (Vogels and Orban 1985). This type of learning is usually referred to as 'perceptual learning.' Compared to other domains of research on learning,

perceptual learning is a relatively new topic, so its definition is even more important than those of topics that were established earlier. Gibson (1963) proposed the following definition for perceptual learning: 'Any relatively permanent and consistent change in the perception of a stimulus array following practice or experience with this array will be considered perceptual learning.' In recent years, one would, in addition, stress the fact that the neuronal mechanisms underlying perceptual learning involve rather 'early' stages of cortical information processing. Learning usually leads to improved performance, but there are exceptions, at least under laboratory conditions with manipulated feedback.

2. Terms Related to Perceptual Learning

Quite a number of processes in the nervous system are able to change their responses to sensory stimulation and there is quite a number of terms related to the term 'learning.' To understand the concept of perceptual learning clearly these terms have to be defined in order to clarify differences and similarities. These related terms include 'plasticity,' 'adaptation,' 'habituation,' 'after-effects,' 'priming,' 'development,' and 'maturation' as well as 'improvement through insight.'

'Plasticity' is defined here as modifiability of functional and anatomical organization of the central nervous system leading to more appropriate function as a result of sensory experience, or to overcome limitations caused by lesions. The term 'adaptation' is most often used in relation to adjustments of information processing within a predefined working range, as a result of stimulation. A classic example is luminance adaptation—adjusting the working range of the visual system to ambient light levels, with no long-term consequences. 'Habituation,' or 'satiation' in the context of rewards, seems to be a special case of adaptation, namely a shift of working range towards lower sensitivity, as in the case of decreased reflex response after repeated stimulation. 'After-effects' can be considered, in many cases, as the result of selective short-term adaptation in cases where perception is the result of antagonistic neuronal channels, as with many after-images. 'Priming' describes the effect of a (sometimes subliminal) stimulus on a subsequent stimulus-reaction pair, or more generally, the effect of initiating a certain type of behavior. The effect of priming is usually short. 'Development' and 'maturation,' unlike learning, ascribe the thrust of the changes in behavior to genetics, not the environment; hence the mechanisms underlying changes of behavior differ radically between these phenomena on one side and perceptual learning on the other. 'Improvement through insight,' as the name indicates, is a term that should be reserved for positive changes of information processing based on cognitive processes, such as one-shot learning.

So what is so special about perceptual learning that earns it a separate entry in this encyclopedia as opposed to a passing mention under the heading 'Learning'? I would like to stress the following difference between 'ordinary' vs. 'perceptual' learning. Most forms of learning to collect better information about the outside world are generally considered to rely on relatively intelligent or complex or cognitive levels of information processing. Hence, learning leading to improved discrimination between sensory stimuli would have been considered only a decade ago to be more of the declarative type of learning (as in learning a poem) than of the procedural type of learning (as in learning to play the piano). Perceptual learning, on the other hand, is a form of learning leading to better use of sensory information which is relatively independent of conscious or declarative forms of learning but relies partly on rather low-level modifications in the central nervous system. Perceptual learning hence resembles, in many respects, procedural forms of learning that are common in motor learning, for example learning to ride a bicycle.

3. Perceptual Learning and Plasticity of Primary Sensory Cortices

This type of low-level modification would have been considered impossible in the 1980s. At this time, the primary visual cortex of adults was considered to be a rather 'hard-wired' first stage of visual information processing, which served to detect and extract certain 'elementary features' from the complex scenes surrounding us (cf. Marr 1982). It was considered to lack plasticity since changing preprocessing during the training of one task might have disadvantageous consequences for solving other perceptual tasks. Indeed, there is direct experimental evidence for a decrease in plasticity of the primary visual cortex during maturation. Hubel and Wiesel (1965) found that covering one eye in young cats leads to changes in their cortical wiring patterns that are reversible during their kittenhood but not thereafter. Similarly, children suffering from a squint may achieve only low visual acuity in the deviating eye; therapy can reverse this loss in small children only. Therefore it seems that a critical development phase exists during which the primary visual cortex is still plastic, but that it loses this plasticity at a later stage of development. Improvement through training in perceptual tasks by adults was therefore supposed to take place on higher levels of cortical information processing.

However, during the last decade of the twentieth century, a number of electrophysiological and psychophysical experiments cast some doubts on this interpretation and suggested that even adult primary sensory cortices showed much more plasticity than was hitherto believed. Some of this evidence will be

presented here. A first example of this evidence was the orientation specificity of improvement through learning. For example, Fiorentini and Berardi (1981) found that discrimination between complex types of grating improved through practice, but that the improvement did not transfer to stimuli rotated by 90 degrees. The same was true for a vernier discrimination task where observers had to indicate whether the lower segment of a vertically oriented vernier stimulus consisting of two almost collinear bars was offset to the right or to the left relative to the upper segment, or whether the right segment of a horizontal vernier was above or below the left segment. Observers improved their performance very significantly during training, but their performance returned to base level when the stimulus was rotated by 90 degrees. Hence, the improvement obtained through training was specific for stimulus orientation.

In a control experiment, the pushbuttons by which observers had to indicate the direction of offset were switched between hands. Observers had to push the left button when a vernier was offset to the right, and vice versa. Results did not deteriorate, indicating that not every change of experimental procedure leads to a drop in performance. Another group of observers were trained in vernier discriminations at eight different positions in the periphery of the visual field for one hour at each position. During that time, they improved performance, but returned to baseline at the transition from one visual field position to the next. The same was true for training vernier discriminations with one eye covered: observers improved their performance through training, but when they performed the same discriminations with the cover moved to the other eye, performance dropped to pretraining levels. The same specificity of improvement for the eye used during training had been observed earlier in a texture discrimination task in which observers had to discriminate a figure from its surround based on the orientation of the stimulus elements (Karni and Sagi 1991). Moreover, improvement did not transfer between a three-dot vernier and a three-dot bisection task, although the stimuli of both tasks differed by approximately one photoreceptor diameter.

4. Neuronal Basis of Perceptual Learning

Hence, the changes of the nervous system underlying these forms of perceptual learning should occur on a quite early level of cortical information processing, in which the neurons are already selective for different stimulus orientations—unlike in the retina—but still partly monocularly activated—unlike in all cortical areas beyond the primary visual cortex. In particular, the eye specificity of improvement points to the primary visual cortex as the most probable site for at least a large part of the changes underlying these forms of perceptual learning.

Recent electrophysiological evidence supports this conclusion of a relatively early site of parts of the neuronal changes underlying perceptual learning. Single-cell recordings in adult monkeys have demonstrated that receptive fields of neurons in the primary visual cortex of adult primates can change position after the parts of the retina that were supplying the input to these cells have been destroyed (Gilbert and Wiesel 1992), that the microcircuitry of the adult visual cortex can change (Eysel 2001), and that the distribution of mass potentials evoked by visual stimulation in humans changes as a result of training, especially pronounced for short latencies and over the primary visual cortex.

5. Different Cortical Levels of Perceptual Learning

Marr's insight is still true—changing the very front end of information processing as a result of learning one perceptual task would necessarily change the processing of many, if not all, other stimuli presented to the same sensors. The speed and amount of learning depend strongly on attentional control, that is on top-down influences within the brain. Hence, present models of perceptual learning increasingly emphasize that learning will occur at quite a number of different levels of information processing, and that top-down influences from 'higher' levels will play a crucial role in adjusting, in a task-dependent way, processing on the 'lower' levels. Recent experiments have indeed provided direct evidence for strong top-down influences on perceptual learning as a result of error feedback and attentional processes (Ahissar and Hochstein 1993, Herzog and Fahle 1998).

It seems that the high specificity of perceptual learning is partly lost if relatively easy tasks are learned, while specificity of improvement is highest for very difficult tasks. A possible explanation is that 'easy' tasks are learned on a relatively 'higher' level of information processing, at which the information extracted from the visual scene is better used after training than was possible before. Difficult tasks, on the other hand, may require changes at lower levels of processing that are specific, for example, to exact visual field position as well as stimulus orientation.

6. Conclusions

To conclude, perceptual learning differs from other forms of learning, especially declarative forms, in that it can be very task- and stimulus-specific, and probably involves functional and anatomical changes even in primary sensory cortices. Though at first sight perceptual learning seems to resemble declarative forms of learning, and to rely on relatively complex cognitive processes, the specificity of improvement for quite low-level attributes such as visual field position,

stimulus orientation, and the eye used for training a visual task indicates a strong and crucial involvement of the primary visual cortex, where neurons are still partly monocularly activated. Dependence on attention, error feedback, and 'insight,' on the other hand, demonstrates that strong top-down influences play a major role in perceptual learning and that perceptual learning also involves more cognitive levels of the brain. Hence, the study of perceptual learning processes not only shows us the amazing amount of plasticity even in adult sensory information processing at a relatively peripheral level, but also leads to a view of cortical information processing not as a feed-forward system of subsequent neuronal layers but as a complex and plastic feedback system with strong and important top-down influences that shape 'lower' or 'early' parts of information processing.

Perceptual Organization

Unless we adopt a rather artificial analytical attitude, we perceive an environment neatly partitioned into objects rather than a mere collection of sensations.

Here is a (red) cherry lying on a (yellow) plate, not merely a blob of red within a yellow surround. The concept of perceptual organization, the grouping of parts into larger units, originated with Gestalt psychology in its attack on the atomistic assumption of structuralism around the beginning of the twentieth century. A then widely held view was that complex percepts are simply additive combinations of sensory elements. Each sensory 'atom' was thought to be independent of all other atoms, tied together to larger complexes just by mechanisms of associative learning. The Gestaltists, on the contrary, emphasized that what we perceive is not 'atomistic' elements, but structured forms and shapes which interact within a perceptual 'field' of dynamic 'forces.' Perception was considered to rely on interactive processes within the nervous system determined by dynamic field forces.

1. Grouping Factors in Vision

Rules for how parts of visual stimuli are grouped together, 'Gestalt laws,' were first formulated by Max Wertheimer (1923) who essentially identified four factors: nearness (proximity), similarity, common fate, and closure.

1.1 Nearness or Proximity

Other factors being equal, the nearer objects are to one another, the more likely they are to be organized into unified percepts. An example is shown in Fig. 1a, where the dots are easily organized into pairs of dots on the basis that each two neighboring dots form a unit. It is almost impossible to see the spaced dots as belonging together or, in other words, to break up the units based on nearness.

1.2 Similarity

The greater the similarity among objects, the more likely they are to be organized into perceptual units. For example, dots of the same color are readily seen as a group in distinction from dots of another color (Fig. 1b).

1.3 Common Fate

Dots which move simultaneously at the same rate and in the same direction, share a common fate, are readily seen as a group. The factor of common fate belongs to the strongest grouping factors; it ties together objects that are quite distant and different in form, size or color, given that they share a sort of event similarity in their sameness of motion. Where grouping would not otherwise occur in stationary displays, it will occur as soon as parts of the display move. A well-camouflaged animal will remain hidden only as long as it is standing still; it becomes visible ('pops out') as soon as it moves.

Figure 1
Demonstration of proximity (a) and similarity (b) as grouping factors

Figure 2
Demonstration of closure as grouping factor

Figure 3
Demonstration of *Einstellung* and past experience as factors in amodal completion

1.4 Closure

Components that constitute a closed entity rather than an open one are more readily organized into a single percept. This factor of closure predicts that a closed line has an advantage over an open one. For example, the two arrangements of four dots in Fig. 2a are seen as a rectangle or diamond rather than as crosses ($\times$) or (+), because the former are closed. Closure also applies to the tendency to complete otherwise incomplete, e.g., partly occluded, objects. The configuration shown in Fig. 2b appears as a trapezoid overlapping a triangle rather than as a complicated eleven-sided figure.

1.5 Subjective Factors

The study of natural camouflage and concealment shows that those grouping factors that refer to objective or stimulus variables fare well in accounting for the utility of various surface markings of animals. In addition, there are subjective or central factors at work, such as an observer's momentary set, or *Einstellung*, and past experience, or custom, in determining how the perceptual field is organized. For example, the three separate lines shown in Fig. 3a may appear, at first glance, as a meaningless geometric arrangement of lines. However, the same configuration, just rotated by 180° (Fig. 3b), will be easily

recognized as a capital E with the missing contours being perceptually completed. Now, if the reader with the *Einstellung* of an 'E' looks back at Fig. 3a, he or she will see a rotated E rather than a mere assembly of three lines. The perceptual formation of an E implies amodal completion of contours in the absence of stimulus (modal) information.

2. Figure–Ground Differentiation

Why do we see things rather than the holes between them? This question addresses another important aspect of organization, the differentiation of the perceptual field into figure and ground. This aspect was first brought out clearly by Edgar Rubin (1915). For example, if we look at a pencil on a desk, the pencil appears as a well-marked part of the perceptual field, the figure, while the desk appears as a relatively formless, featureless mass which we call the ground. The figure has the character of a thing, whereas the ground appears like unformed material. The ground seems to extend continuously behind or, sometimes, in front of the figure, i.e., although the figure usually appears in front, the ground is not always identical with background. For example, in looking through a window at a tree, the window screen appears as ground, but is clearly seen in front of the figure, the tree.

2.1 Dynamics of Figure–Ground Perception

Rubin pointed out that even if all parts of a configuration are grouped together properly, it can appear

either as object (figure) or surface (ground) under certain conditions. These so-called ambiguous or reversible figures 'flip' when, for example, the attention is directed to a specific point on the stimulus pattern. The dynamics of figure–ground perception due to the multivalence of the stimulus field are impressively demonstrated in a pattern shown in Fig. 4 (from Spillmann and Ehrenstein 1996)

New 'flowers' (figures) rise from the 'meadow' (ground) and disappear again, illustrating the vain attempt to establish a tendency toward a better and more stable percept. Apparently, the pattern allows for several groupings of equal probability and hence perception fails ever to reach a steady state. This example nicely illustrates that the visual space, as Kanizsa (1979, p. 181) artfully put it, is not a static geometrical scheme, nor is it a simple transposition on the perceptual level of the topographical arrangement of the retinal stimulus, but rather should be considered the result of an extremely dynamic event.

2.2 Tendency Towards *Prägnanz*

The Gestaltists assumed that the process of figural segregation and differentiation would follow a general tendency towards figural goodness or *Prägnanz* (Wertheimer), which denotes a processing principle for percepts to become structured in the most regular, symmetrical, and simple manner possible under the prevailing stimulus conditions. This process was understood by Wolfgang Köhler as a kind of self-organization according to electrodynamic field forces inherent in the sensory system. 'In all processes which terminate in time-independent states the distribution

Figure 4

A pattern which affords a never-ending fluctuation in grouping (after Spillmann and Ehrenstein 1996)

shifts towards a minimum energy' (Köhler 1920, quoted from Koffka 1935, p. 108). More than any other principle, the tendency towards *Prägnanz* emphasizes the global aspects of perceptual organization, since even minor local changes in the stimulus or in the observing process (such as eye movements or changes in attention) can result in a reorganization of the entire percept (see Fig. 4). A modern approach to the problem of self-organization and *Prägnanz* can be found in the theory of neural synergetics with its tendency towards ordered steady states in dynamic vector fields (Haken and Stadler 1990).

3. Perceptual Organization in Other Sense Modalities

Although the principles of perceptual organization have been studied most thoroughly for the visual modality, they also apply to other sense modalities. For auditory perception, Bregman (1990) has provided many examples demonstrating the resemblance between audition and vision. Temporal proximity of tones is more important than spatial proximity: Tones that follow each other close together in time are perceived as belonging together. Similarity is determined primarily by the pitch of tones: tones similar in pitch tend to be grouped together in perception. When a sequence of alternating high- and low-frequency tones is played at a certain rate, listeners are able to follow the entire sequence of tone, provided that the frequency difference between tones is small and the tones are played at a slow rate. With greater frequency differences or higher rates, however, the sequence splits into two streams, one high and one low in pitch (auditory stream segregation).

Other examples—studies in tactile perception, for instance—confirm the notion that the above-mentioned factors of perceptual grouping play a similar role in different modalities. This suggests that the perceptual system can utilize organizing principles from one sensory modality to the other, i.e., in a cross-modal way. Moreover, cross-modal interactions can change the percept. A recent example concerns the perception of emotions. Listeners having to judge the emotion in the voice are influenced by whether the (visually displayed) face expresses the same emotion or a different one (De Gelder and Vroomen 2000).

4. Neural Correlates of Perceptual Organization

More than 70 years after Wertheimer's pioneering formulation of perceptual grouping factors, terms that were originally introduced to describe qualitatively properties of figural grouping and segregation are being used as a much-needed vocabulary for interpret-

ing spatiotemporal processing of sensory neurons and neuronal systems. The Gestaltists themselves, notably Wolfgang Köhler, tried to link perceptual organization to brain processes. Inspired by the laws of thermodynamics, the brain was thought to be a homogeneous conductor of bioelectric forces rather than a complex network of interacting neurons (e.g., Köhler and Held 1949). However, the field forces postulated by Köhler as factors in perceptual organization could not be substantiated by physiological evidence. Neural correlates of perceptual grouping are today assumed to consist of receptive field organization and synchronized coupling of neuronal activity within and across cortical areas (e.g., Spillmann and Ehrenstein 1996).

4.1 Receptive Field Organization: A Micro-Gestalt

The processing of sensory input obeys essentially two principles, convergence and divergence. Many receptors send their input to the same ganglion cell (convergence) and conversely one and the same receptor distributes signals to several ganglion cells (divergence). The receptor surface area within which a change of stimulation can modify the firing rate of a given neuron is called its receptive field. In vision, receptive fields of retinal, geniculate, and cortical neurons are concentrically organized with an excitatory center and an inhibitory surround (on-center neurons) or with a center that is inhibited by light and a surround that is activated by light (off-center neurons). The functional unit represented by the receptive field (with its center-surround antagonism and selective spatial and temporal sampling) is a basic neuronal mechanism that achieves non-additive integration of stimulus input. It has therefore been considered a micro-Gestalt by Spillmann and Ehrenstein (1996) with the conjecture that perceptual organization is largely determined by receptive-field organization.

4.2 A Neurocomputational Example

A detailed neurocomputational model of how perceptual groupings might emerge from interactions of cells with known receptive-field properties of the lateral geniculate and cortical areas V1 and V2 has been recently proposed by Grossberg et al. (1997). For example, global properties of Gestalt grouping (as demonstrated in Fig. 5) can be accounted for by their model that involves multiple levels of thalamo-cortical interaction to generate emergent boundary groupings.

The left side of Fig. 5 (from Grossberg et al. 1997) shows an ambiguous configuration (A, upper part) which allows the perception of vertical or horizontal groupings of bar elements and the simulated outcome

Figure 5
Perceptual grouping: above stimulus patterns A and B, below the perceived grouping as predicted by the model (after Grossberg et al. 1997)

by the neurocomputational model (A, lower part). Adding horizontal bar elements (Fig. 5, B) leads to horizontal grouping in perception (upper part) and also in the model (lower part).

4.3 'Perceptive' Neurons and Synchronized Coupling of Spike Activity

In a few cases 'perceptive' neurons (Baumgartner 1990) have been reported that mediate invariant stimulus properties, e.g., neurons in area V4 of primate cortex seem to signal the perceived color of a stimulus, irrespective of its spectral composition and changes in illumination. The striking correlations between the activity of highly specialized single neurons and complex perceptual performance support the view that neurons at higher levels in the processing hierarchy may be sufficient to convey Gestalt perception. However, search for individual neurons responding selectively to complex configurations has, so far, revealed a very limited set of biologically significant stimuli. Alternatively, synchronized oscillations of even far-distant neurons allow for perceptual coherence over a large area of the sensory field. The above-mentioned grouping factor of common fate could especially be accounted for by temporal binding of features (e.g., Eckhorn 1999). In fact, synchronized coupling of spike activity between remote brain areas has been found to be context-dependent and to account for spatiotemporal coherence in perception. Moreover, synchronized feature binding affords individual cells and cell groups flexibly to change partners with which they share activity when the stimulus configuration changes. Thus, single-cell ac-

tivity, organized within a hierarchy of receptive fields, and synchronized feature binding seem to provide the basic neural mechanisms subserving perceptual grouping.

Performance: Anthropological Aspects

Anthropology uses the concept of performance to refer to distinctive events or aspects of behavior, contributing to the understanding of human behavior in traditional, nontraditional, and avant-garde con-

texts. The current applications range from the most extraordinary and stylized forms of human behavior to the fundamental routines of everyday life, and address different areas of specialized professionalism and expertise, in ritual, commercial, economic, medical, dramatic, and sportive spheres. Initially driven by a theoretical concern with social function and meaning, contemporary research uses the performance concept to address issues of identity and the relationship between performance, self, researcher, and social space.

1. Development of the Concept

Performance as an anthropological concept developed after the 1950s. Previously, anthropologists subsumed performance into the analysis of ritual. In British social anthropology, which had built its reputation as a science of total functioning systems and structures centred on kinship networks, specialized forms of human behavior occurring within modern or commercial venues, such as acting or dancing, were considered marginal subjects. By the mid-1960s, however, broader humanist concepts of culture, more powerful in anthropology elsewhere in Europe and in the USA, allowed the concept of performance to enter more centrally into anthropological analyses.

The American sociologist Erving Goffman (1956, p. 23) developed a model in which social interaction was explicable as acts and performances: 'The world, in truth, is a wedding,' and performance is 'all of the activity of a given participant on a given occasion which serves to influence in any way any of the other participants' (Goffman 1956, p. 8). Goffman unified the analysis of roles and situations using theatrical metaphors such as front and back stage to explain different aspects of behavioral presentation and 'multiple versions of reality.' This model was intended as a fifth analytical perspective to complement existing technical, political, structural, and cultural ones. This dramaturgical and transactional vision of social interaction remains influential.

Milton Singer, Dell Hymes, Clifford Geertz, and Victor Turner have also shaped the ways in which anthropologists use performance notions metaphorically to explain social action as a complex system of symbolic and meaningful behavior which produces an ordered understanding of the world (Geertz 1973). Performance in these terms is not limited to representation, but is an active and creative precondition for social life.

Victor Turner's work has been particularly influential on current uses of performance. He moved from a functionalist study of ritual to cultural performance models and finally to theatrical performance itself, though performance was never separated completely from ritual, a 'transformative performance revealing major classifications, categories, and contradictions of

cultural process' (Ronald L. Grimes, cited in Turner 1986, p. 75). Turner developed three linked explanatory concepts. 'Ritual process' consists of separation, transition or liminality, and reintegration. Anti-structure or 'communitas' contrasts with the structure of everyday life and describes the creative and expressive behavior associated with a generalized notion of liminality beyond the simple process of a specific ritual event. 'Social dramas' extend the ritual process into other kinds of social scenario. This framework merged the borders between initiation rituals, social events such as carnivals, and particular theatrical performances, as what Wilhelm Dilthey called 'lived experience' (Turner 1986, pp. 84–90).

Turner was part of Max Gluckman's 'Manchester School' of anthropology, but he has been more influential in the USA than others from this school. Other scholars of this background produced actor-centered transactional and conflict models using performance perspectives on more political topics, often drawing on Marxist theory. In his study of London's Notting Hill Carnival, Abner Cohen (1993) reaffirms his interest in performance as part of a wider analysis of the relationship between cultural forms and political formations: performance as a part of political symbolism is interesting because of the contradictions between the two dimensions of social interaction: the unintentional and moral nature of cultural action, and the amoral self-interest of political action. Cohen's work has influenced the analysis of performance as a political tool in postcolonial societies where processes of retribalization and issues of ethnic identity have been so dominant (Parkin et al. 1996).

The study of cultural performances has been inflected towards ritual and personal transformation, or towards contradictions and political conflict, although the proponents of each 'side' would all claim to be attempting to bridge such dualisms. None the less, labels such as 'humanist' and 'Marxist' continue to limit any such transcendence, despite the best efforts of those who have insisted on the multiplicity of social life (Tambiah 1985).

Other salient influences came from sociolinguistics. Theories which characterized communication as performative, and not just informative, were inspired by Jakobson's 'poetic function'—'the way in which a communication is carried out' (Bauman 1986, p. 3)—and Austin and Searle's speech act theory. For instance, Richard Bauman (1986, p. 112) has analyzed American folk narratives using a framework of story, performance, and event. This specialized use of performance has been very influential in establishing the performative dimensions of different kinds of communication, particularly in the study of competence and play. Anthropologists have also developed communicative approaches to the performance of metaphor in various social contexts (Fernandez 1986). Such work on verbal performance has influenced general theories of performance in human behavior,

but although it has moved away from a text-based model, it has produced somewhat disembodied accounts of performance, with little reference to the nonverbal gestural dimension of human communication and expression.

2. Methodological Innovations

These influences have legitimized performance as a topic within anthropology, and Turner's last writings on performances as liminoid phenomena have promoted an interest in nontraditional performance, overlapping with performance studies and cultural studies. There has also been a belated recognition of the importance of embodied behavior and bodily techniques.

Increasing attention is being paid to different performance skills and genres, not simply as objects of study but also methodologically. Anthropology has always been a discipline which attracts people with an experience of life outside academe, and the 1980s saw the emergence of performer-anthropologists, scholars who had previously worked on the stage professionally as dancers and actors. Anthropologists who have not been professional actors or dancers may choose to include training in performance as part of their research, using their bodies to explore familiar or unfamiliar techniques self-consciously by learning alongside aspiring professionals and experts. This recognition of the importance of embodiment is part of a broader trend to understand human knowledge as a reflexive situated practice, validated not by observation, but by experience (Hastrup 1995, p. 83).

The traditional anthropological interest in ritual which Turner extended to theater also resulted in an intellectual collaboration with Richard Schechner, a theatre director and academic. After Turner's death in 1983 Schechner kept the effort alive, both practically and theoretically. The continuum between performance with ritual efficacy and theatrical performance rests on the theory that performance is 'restored behavior', strips of behavior with 'a life of their own', which can be rearranged or reconstructed independently of the various causal systems which brought them into existence (Schechner 1985, p. 35).

Schechner has played an important role in forging a meeting between the performers, anthropologists and other researchers of intercultural performance. This wide and fuzzy interdisciplinary field has become well established in the USA and is gaining momentum in the UK and Europe. The International School of Theatre Anthropology founded by Eugenio Barba and Nicola Savarese has involved performers from Japan, India, Indonesia, and Brazil. Theater anthropology is not the study of the performative phenomena by anthropologists, but rather the study of the pre-expressive behavior of the human being in an organized performance situation (Barba 1995, p. 10).

In 1990, the anthropologist Kirsten Hastrup's life story was 'restored' (to use Schechner's term) as a drama, *Talabot* by Barba's Odin Teatret (Hastrup 1995, pp. 123–45). New and established anthropologists are also turning to different performance arenas, including cinema, television, and the internet, to explore further permutations of sociality which would have been unimaginable a hundred years ago (Hughes-Freeland and Crain 1998).

Anthropological analyses and uses of performance are not limited to the technicalities of theater and acting. Johannes Fabian (1990) has argued that performance must deal with the political, and has worked with a theater troupe in Zaire to explore local concepts of power through drama and television. The sociolinguistic approach to performance has also been applied to analyze powerful speaking in Sumba, East Indonesia, which has been repressed by the State and transformed into textbook culture (Kuipers 1990). The social processes of power are also the center of Ward Keeler's (1987) study of shadow puppet theatre in Java. Studies such as these are found among the ethnography of every region, and often remain independent of the meeting between anthropology and performance studies.

The relationship between ritual and performance is generating approaches to the study of healing in a number of interesting ways. Such studies use transactional and conflict models but also consider the power of the aesthetic and expressive dimensions of performance in the face of political repression or disenfranchisement. For example, the healing power of comedy in an exorcism in Sri Lanka restores the sick person to a sense of social integration, in line with G. H. Mead's theory (Kapferer 1991). Michael Taussig (1993) invokes Marx and the Frankfurt School to explore mimetic behavior which lies at the heart of shamanic healing and social imagery, simultaneously representing and falsifying the world, and demonstrates how irrationality is being performed at the heart of the everyday. 'Mimetic excess' creates 'reflexive awareness', which makes connections between history, make-believe, and otherness.

Bureaucratic resistance to the irrational is also at issue, as in the case of professional female performers in Indonesia, who had the power to mediate between the village spirit made manifest by the village elder and the community, and brought healing and protective energies to local communities (see Fig. 1). These performers are being made extinct by the processes of state education and professionalization, which tend to deny female power (Hughes-Freeland 1997).

Performance here differs from the rational calculation of Goffman's social agents, and introduces complexity into the debate about the extent of individual human choice and intentionality. Such explorations are a reminder of the continuing usefulness of studying ritual performance to understand how humans express their possession and dispossession,

Figure 1
Female dancer in Java protects a baby with face powder

and the permeability of the boundary between ritual performance and artistic performance.

More radically, anthropologists have applied healing processes from other cultures to help the sick at heart in their own societies by means of 'a theatre model of dramatherapy' (Jennings 1995, p. xxvii). While Aristotle's concept of catharsis may seem universal, different theatres produce forms of what Sue Jennings (1995, p. 185) calls 'abandonment', which vary greatly in their effects and forms of control. Ultimately it is this variation which must concern the anthropologist.

3. Central Issues

During the 1970s, the anthropological project was framed by questions about function and meaning, but these have been superseded by concerns with identity and experience. Performance is productive of individuals, with gendered, ethnic, or other specified markers of social identity. It has also been argued that it produces the experience of society as a continuum (Parkin et al. 1996, p. xvii). By using the performance concept in a heuristic manner, anthropologists are

able to develop insights into the acquisition of competence, as general socialization or as training to acquire particular skills, and to further their understanding of social interactions and formations.

The central problem facing anthropologists working on, and by means of, performance remains the question of boundaries. The topic continues to stimulate argument: is performance a discrete category, or is it an aspect of everyday behavior? How does performance help us to understand reality? (Hughes-Freeland 1998, pp. 10–15).

An interesting debate about performance is the extent to which human action is scripted or emergent. Is performance best understood as mimesis and imitation, or as *poesis*, creative, emergent, and transformative? Anthropological self-critiques are often formulated along the lines of performance models vs. textual models, and argue for process models vs. structural ones. One party stresses the determinacy of form, the other gives primacy to emergence, praxis, experience. These arguments situate performance centrally within current polemics about anthropological knowledge, and whether it should represent itself as operating within a system of models and rules, or performatively and dialectically. Anthropologists

now approach performance as being risky and interactive, rather than determined and predictable, using active and participatory models of spectatorship, not passive ones, on a continuum of general varieties of human interaction.

Some commentators have questioned the general applicability of the Western view of performance as illusion, as theatrical, as unfactual, since such a view does not necessarily accord with the ways in which activities categorized as performances by anthropologists may be understood by members of the societies in which they occur (Schieffelin 1998). Others by contrast suggest that the exposure of the acting body makes deception impossible (Hastrup 1995, p. 91). By questioning critically the presuppositions supporting categorical oppositions implied in performance, such as pretense vs. authenticity, and by going against the grain of their own cultural presuppositions, anthropologists are able to construct descriptions of alternative ways of seeing and being in the world, and to celebrate the diversity of human cultural experience despite its shared biophysical nature. Anthropologists thus differ in their treatment of performance from those working in other disciplines.

4. Future Directions

As human interaction intensifies across time and space, anthropological approaches to performance recognize the complexity of contemporary life and the superficiality of dichotomizing the 'everyday' vs. 'ritual' realities. Information and media technologies facilitate virtual realities, and complicate the different ways in which performance may be transmitted and received, beyond the defined space-time continua of theatre, ritual arena, or event. Technological innovations in this way make it necessary for the analysis of performance to spill over again from specialized behavioral contexts into emergent everyday lives ((Hughes-Freeland and Crain 1998).

Visual technologies can bring all kinds of performance to us in nonverbal ways, unmediated by words, using images instead. Although these images are not pure imitations of the performances as they occur, it could be argued that the researcher is freer to respond directly to the performance than when reading about it. For example, Jean Rouch's film of the Hauka possession cult in Ghana in 1953, *Les Maîtres Fous* (*The Mad Masters*) presents images which language might fail to represent as convincingly real. Experimental ethnographic explorations of the relationship between embodied performance and text suggest innovative and exciting approaches to issues of analysis and representation in anthropology.

The potential fields for the development of anthropological approaches to performance are numerous. The study of linguistic performance has already been employed in communication analyses in the field

of artificial intelligence, a development which might extend to understandings of embodied performance. The anthropology of performance, perhaps the most ostensibly humanist of the new sub-areas of anthropology, could move increasingly into the field of medical and information technologies, theoretical and practically. In the more immediate future, anthropologists work to develop a less culturally entrenched view of human performance activities, and engage in intracultural or cross-cultural performances to promote wider understanding about the different ways of acting human within the constraints of the group, and the challenges performance presents to those constraints.

Performance Evaluation in Work Settings

Job performance is probably the most important dependent variable in industrial and organizational psychology. Measures of job performance are typically employed for many research and practice applications. Examples are evaluating the effects of a training program or a job redesign effort on job performance, and assessing the validity of a selection system for predicting performance. For these and other personnel-related interventions, what is needed are accurate measures of job performance to assess the effectiveness of the intervention.

This entry first introduces the concept of criterion relevance and other 'criteria for criteria.' The second topic discussed is the issue of whether work performance is best characterized by multiple criteria or by a composite criterion, that is, a single summary index of performance, and third, methods of measuring criterion performance are presented. Finally, what appear to be the most important future directions in describing and measuring work performance are highlighted.

1. Criterion Relevance and Other Standards for Criteria

What differentiates good from poor criterion measurement? That is, what are the most important features of good criteria? The most important is relevance. Relevance can be defined as the correspondence between criterion measures and the actual performance requirements of the job. Criterion measures should reflect all important job performance requirements. Useful in this context are the terms deficiency and contamination. Deficiency for a set of criterion measures occurs when the set is relevant to only part of the criterion domain. A job knowledge test for an insurance agent will probably fail to cover the interpersonal skill part of the job. Contamination refers to a criterion measure tapping variance in performance beyond the control of the organization member. For example, sales volume for account executives may be based in part on their performance, but also on how easy it is to sell the product in their own territory. A perfectly relevant set of criterion measures is neither contaminated nor deficient.

The second most important standard for good criterion measurement is reliability. Criterion scores should be consistent over, at least, relatively short time

intervals. For example, if a criterion measure for fast food servers is ratings of customer service quality by multiple customers, we would like to see consistency (i.e., reliability) in how different customers rated the servers, with good performers in this area rated consistently high, poorer performers, consistently lower, etc. There are other criteria for criteria that some authors have mentioned (e.g., acceptability of measures to the sponsor) but relevance and reliability are clearly the most important.

2. Multiple and Composite Criteria

An issue in measuring work performance is whether a single criterion should represent the performance requirements of a job or whether multiple criteria are required. Advocates for a single composite criterion see criteria as economic in nature, whereas supporters of multiple criteria view them more as psychological constructs. Probably the best way to resolve the issue is to recognize that the purpose of performance measurement largely dictates the appropriateness of the two views (Schmidt and Kaplan 1971). For example, when making compensation decisions for a unit's members based on performance, it is necessary to obtain a single performance score at some point for each employee. To make these decisions, we need an index of overall performance, worth to the organization, or some similar summary score. On the other hand, if the goal is to understand predictor-criterion links in personnel selection research, for example, then using multiple criteria and examining relationships between each predictor (e.g., ability, personality, etc.) and each criterion (e.g., technical proficiency) is probably most appropriate.

A related issue is the empirical question of how highly correlated multiple criteria for a job are likely to be. If correlations between criterion measures are high, then a single composite measure will be sufficient to represent the multiple criteria. On balance, research suggests that most jobs have multiple performance requirements. Performance on these multiple dimensions may be positively correlated but not so highly that distinctions between dimensions are impossible.

An attempt has been made to identify the criterion constructs underlying performance across jobs. Campbell et al. (1993) argue that eight dimensions (i.e., Job Specific Technical Proficiency, Non Job Specific Technical Proficiency, Written and Oral Communication, Demonstrating Effort, Maintaining Personal Discipline, Facilitating Peer and Team Performance, Supervision/Leadership, Management /Administration) reasonably summarize the performance requirements for all jobs in the US economy. Not every job has every dimension as relevant, but the eight dimensions as a set reflect all performance requirements across these jobs. Criterion research in

Project A, a large-scale selection study in the US Army, empirically confirmed several of these dimensions for 19 jobs in the Army. More will be said about these kinds of criterion models in the section entitled Future.

A final issue in this area focuses on the boundaries of 'work performance.' How should we define performance? Recent attention has been directed toward organizational citizenship behavior (OCB), prosocial organizational behavior, and related constructs (e.g., Organ 1997) as criterion concepts that go beyond task performance and the technical proficiency-related aspects of performance. For example, the OCB concept includes behavior related to helping others in the organization with their jobs and conscientiously supporting and defending the organization. Research has shown that supervisors making overall performance judgments about employees weight OCB and similar constructs about as highly as these employees' task performance (e.g., Motowidlo and Van Scotter 1994). Also, a link between OCB on the part of organization members and organizational effectiveness has some empirical support (e.g., Podsakoff and MacKenzie 1997).

3. Methods of Measuring Criterion Performance

Two major types of measures are used to assess criterion performance: ratings and so-called objective measures. Ratings—estimates of individuals' job performance made by supervisors, peers, or others familiar with their performance—are by far the most often used criterion measure (Landy and Farr 1980). Objective measures such as turnover and production rates will also be discussed.

3.1 Performance Ratings

Performance ratings can be generated for several purposes, including salary administration, promotion and layoff decisions, employee development and feedback, and as criteria in validation research. Most of the research on ratings has focused on the latter for-research-only ratings. Research to be discussed is in the areas of evaluating the quality of ratings, format effects on ratings, and different sources of ratings (e.g., supervisors, peers).

3.1.1 Evaluation of ratings. Ratings of job performance sometimes suffer from psychometric errors such as distributional errors or illusory halo. Distributional errors include leniency/severity where raters evaluate ratees either too high or too low in comparison to their actual performance level. Restriction-in-range is another distributional error. With this error, a rater may rate two or more ratees

on a dimension such that the spread (i.e., variance) of these ratings is lower than the variance of the actual performance levels for these ratees (Murphy and Cleveland 1995). Illusory halo occurs when a rater makes ratings on two or more dimensions such that the correlations between the dimensions are higher than the between-dimension correlations of the actual behaviors relevant to those dimensions (Cooper 1981).

A second common approach for evaluating ratings is to assess interrater reliability, either within rating source (e.g., peers) or across sources (e.g., peers and supervisor). The notion here is that high interrater agreement implies that the ratings are accurate. Unfortunately, this does not necessarily follow. Raters may agree in their evaluations because they are rating according to ratee reputation or likeability, even though these factors might have nothing to do with actual performance. In addition, low agreement between raters at different organizational levels may result from these raters' viewing different samplings of ratee behavior or having different roles related to the ratees. In this scenario, each level's raters might be providing valid evaluations, but for different elements of job performance (Borman 1997). Accordingly, assessing the quality of ratings using interrater reliability is somewhat problematic. On balance, however, high interrater reliability is desirable, especially within rating source.

A third approach sometimes suggested for evaluating ratings is to assess their validity or accuracy. The argument made is that rating errors and interrater reliability are indirect ways of estimating what we really want to know. How accurate are the ratings at reflecting actual ratee performance? Unfortunately, evaluating rating accuracy requires comparing them to some kind of 'true score,' a characterization of each ratee's actual performance. Because determining true performance scores in a work setting is typically impossible, research on the accuracy of performance ratings has proceeded in the laboratory. To evaluate accuracy, written or videotaped vignettes of hypothetical ratees have been developed, and target performance scores on multiple dimensions have been derived using expert judgment. Ratings of these written vignette or videotaped performers can then be compared to the target scores to derive accuracy scores (Borman 1977).

3.1.2 Rating formats. A variety of different rating formats have been developed to help raters evaluate the performance of individuals in organizations. Over the years, some quite innovative designs for rating formats have been introduced. In this section we discuss two of these designs: numerical rating scales and behaviorally anchored rating scales.

It may seem like an obvious approach now, but the notion of assigning numerical ratings in evaluating

organization members was an important breakthrough. Previously, evaluations were written descriptions of the ratee's performance. The breakthrough was that with numerical scores, ideally, well informed raters could quantify their perceptions of individuals' job performance, and the resulting scores provide a way to compare employees against a standard or with each other.

One potential disadvantage of numerical scales is that there is no inherent meaning to the numbers on the scale. To address this difficulty, Smith and Kendall (1963) introduced the notion of behaviorally anchored rating scales (BARS). These authors reasoned that different levels of effectiveness on rating scales might be anchored by behavioral examples of job performance (e.g., always finds additional productive work to do when own normally scheduled duties are completed—high performance level on Conscientious Initiative rating dimension). The behavioral examples are each scaled according to their effectiveness levels by persons knowledgeable about the job and then placed on the scale at the points corresponding to their respective effectiveness values, helping raters to compare observed performance of a rater with the behavioral anchors on the scale, in turn leading to more objective behavior-based evaluations.

3.2 Rating Sources

Supervisors are the most often used rating source in obtaining performance evaluations of organization members. An advantage of supervisory ratings is that supervisors typically are experienced in making evaluations and have a good frame of reference perspective from observing large numbers of subordinates. A disadvantage is that in at least some organizations supervisors do not directly observe ratee performance on a day-to-day basis. In addition, coworker or peer ratings are sometimes used to evaluate performance. A positive feature for peer ratings is that coworkers often observe employee performance more closely and more regularly than supervisors. A difficulty is that coworkers are less likely than supervisors to have experience evaluating ratee performance.

Other rating sources may also be involved in assessing job performance. In fact, a recent emphasis has been toward the concept of '360° ratings,' augmenting supervisory ratings with evaluations from peers, subordinates, self-ratings, and even customers' assessments. The general idea is to assess performance from multiple perspectives so that a balanced evaluation of job performance might be obtained (Bracken 1996).

3.3 Objective Criteria

A second major measurement method for criterion performance involves use of objective criteria. Ob-

jective criteria employed in personnel research include turnover, production rates, and work samples of employee performance. At first glance, one may presume that objective criteria are more desirable than ratings, which are inherently subjective. Unfortunately, judgment often enters into the assignment of objective criterion scores. Also, objective measures are often contaminated as criteria, with problems such as factors beyond the assessee's control influencing these outcome measures. Nonetheless, when they are relevant to important performance areas and are reasonably reliable and uncontaminated, objective measures can be useful in indexing some criterion dimensions.

3.3.1 Turnover. Turnover or attrition is often an important criterion because the cost of training replacement personnel is usually high (e.g., Mobley 1982); also, having people, especially key people, leave the organization can be disruptive and can adversely affect organizational effectiveness. Turnover is sometimes treated as a single dichotomous variable—a person is either a 'leaver' or a 'stayer.' This treatment fails to distinguish between very different reasons for leaving the organization (e.g., being fired for a disciplinary infraction versus leaving voluntarily for health reasons). Clearly, turnover for such different reasons will have different patterns of relationships with individual difference or organizational factor predictors. Prediction of turnover with any substantive interpretation requires examining the categories of turnover. It may be, for example, that employees fired for disciplinary reasons have reliably different scores on certain personality scales; e.g., lower socialization, compared to stayers, whereas prior health status is the only predictor of leaving the organization for health reasons. This approach to dealing with turnover as a criterion variable, appears to offer the most hope for learning more about why individuals leave organizations and what can be done to reduce unwanted turnover.

3.3.2 Production rates. For jobs that have observable, countable products that result from individual performance, a production rate criterion is a compelling bottom-line index of performance. However, considerable care must be taken in gathering and interpreting production data. For example, work-related dependencies on other employees' performance or on equipment for determining production rates may create bias in these rates. Also, production standards and quota systems (e.g., in data entry jobs) create problems for criterion measurement.

3.4 Work Sample Tests

Work sample or performance tests (e.g., Hedge and Teachout 1992) are sometimes developed to provide

criteria, especially for training programs. For example, to help evaluate the effectiveness of training, work samples may be used to assess performance on important tasks before and after training. Such tests can also be used for other personnel research applications, such as criteria in selection studies.

Some argue that work sample tests have the highest fidelity for measuring criterion performance. In a sense, the argument is compelling: What could be more direct and fair than to assess employees' performance on a job by having them actually perform some of the most important tasks associated with it? In fact, some researchers and others may view work samples as ultimate criteria—that is, *the* best and most relevant criterion measures. Performance tests should not be thought of in this light. First, they are clearly maximum performance rather than typical performance measures. As such, they tap the 'can-do' more than the 'will-do' performance-over-time aspects of effectiveness. Yet 'will-do,' longer-term performance is certainly important for assessing effectiveness in jobs. Accordingly, these measures are deficient when used exclusively in measuring performance. Nonetheless, work samples can be a useful criterion for measuring aspects of maximum performance.

3.5 Conclusions

The following conclusions can be drawn about criteria and criterion measurement methods.

3.5.1 Performance ratings. Ratings have the inherent potential advantage of being sensitive to rater performance over time and across a variety of job situations. Ideally, raters can average performance levels observed, sampling performance-relevant behavior broadly over multiple occasions. Provided observation and subsequent ratings are made on all important dimensions, ratings can potentially avoid problems of contamination and deficiency. Of course, these are potential advantages of the rating method. Rater error, bias, and other inaccuracies, must be reduced in order for ratings to realize this potential. Both basic and applied research are needed to learn more about what performance ratings are measuring and how to improve on that measurement.

3.5.2 Objective measures. Like other methods of measuring criterion performance, objective measures can be useful. However, these measures are almost always deficient, contaminated, or both. Indices such as turnover and production rates produce data pertinent to only a portion of the criterion domain. In addition, some of these indices are often determined in part by factors beyond the employee's control.

Regarding work sample tests, the point was made that these measures should not in any sense be considered as ultimate criteria. Nonetheless, well-conceived and competently constructed performance tests can be valuable measures of maximum, 'can-do' performance.

3.6 The Future

An encouraging development in criterion measurement is the consideration of models of work performance (e.g., Campbell et al. 1993). As mentioned, models of performance seek to identify criterion constructs (e.g., Communication, Personal Discipline) that reflect broadly relevant performance requirements for jobs. Such criterion models can help to organize accumulating research findings that link individual differences (e.g., ability and personality), organizational variables (e.g., task characteristics), and the individual criterion constructs identified in the models. In addition, efforts should continue toward learning more about what performance ratings and objective performance indexes are measuring, with the goal of improving the accuracy of these measures. Improving the measurement of work performance is critically important for enhancing the science and practice of industrial–organizational psychology toward the broad and compelling objective of increasing the effectiveness of organizations.

Person and Self: Philosophical Aspects

Few terms like 'person' and 'self' in the course of history have proven to be more difficult to pin down to an unequivocal meaning. Furthermore, both are among the terms of most common usage, yet their exact meaning can prove quite elusive. More than offering an exhaustive definition and an exhaustive reconstruction of the history of the notions of 'person' and 'self,' it is sensible to attempt here to offer an account of the scope of variation in their usage as well as an account of the different problems that different authors and traditions have associated with them.

1. Person and Self Contrasted

To complicate things further, there is no settled account of the relation *between* 'person' and 'self.' The term 'person' has for a long time been the prevailing one for referring to a single human being. The onset of modernity marks the beginning of its relative obsolescence and its gradual replacement by the term 'self,' and sometimes 'individual,' at the center of the debates within the social sciences and social and political philosophy. Over the past few centuries the term 'person' has almost disappeared from the vocabulary of the social sciences, only to undergo a sort of revival, sometimes tinged with religious overtones,

in the existentialist and so called 'personalist' philosophical currents of the twentieth century.

Modern social theory has operated rather with the notion of the individual since the time of Hobbes (*Hobbes, Thomas (1588–1679)*) and Locke (*Rokkan, Stein (1921–79)*) and then later, starting with Cooley's and Mead's (*Luria, Aleksander Romanovich (1902–77)*) symbolic interactionist perspective, it has widely adopted the concept of the self. Today a further evolution is perhaps under way: the concept of the person is regaining center stage. In contemporary political philosophy John Rawls, for example, bases his view of political liberalism on a political conception of the *person*, not of the self or of the individual. In order to grasp these vicissitudes of the two terms, one has to look at some of the main turning points in their evolution.

Etymologically the term 'person' originated at the crossroads of the ancient Greek and Roman civilizations. In ancient Greek *prós-opon* (literally 'placed in front') designated the artificial face, the mask that actors used to wear on stage when performing tragedies. The Latin verb *personare* also alluded to the realm of the performing arts: it meant to 'sound through,' to let the voice reach out to the watching and listening public through the mask. Metaphorically, then, in its origins the term person carries a trace of the willful appearance for the sake of others. But the Roman civilization also grafted a legal connotation on the term 'person': the legal person was another sort of mask, the individual human being in her or his capacity as bearer of rights, privileges, prerogatives but also duties and obligations. In that sense to be a self without being a legal person would be tantamount to being nothing. Typically, in these public-minded cultures the sphere of the private was designated by terms such as *idiotes* and *privatus* both of which carried a diminishing connotation—they presupposed that something was somehow missing.

Sometime during the Hellenistic period and at the apex of the Imperial Age a shift of meaning began to occur. The increase in complexity and the somewhat more anomic quality taken by social life in the Hellenistic monarchies and in Imperial Rome, the increase in complexity of the political apparatus alongside with the more despotic and arbitrary styles of government, the increasing religious eclecticism of the Roman public world, and the appearance of the Christian ethos of holiness and personal sanctity, all contributed to the rise of a cleft between *public* and *private* life and to a new distribution of value across that divide. Stoic philosophers like Seneca, Epictetus, and Marcus Aurelius on the one hand, and the early Christians on the other, were at one in regarding with suspicion what now appeared as a realm of merely public, artificial, contrived personal masks or roles. Inwardness and depth belonged to the self, whereas the person stood now for convention, tradition, custom, and superficial appearance. This new relation

between the two terms continued to dominate throughout the Middle Ages (Augustine, Erasmus), the Renaissance and the Reformation (Luther).

Another major shift occurred with the rise of modern political philosophy, the rise of the modern notion of rights and the modern conception of citizenship. Whether the focus was on the capacity for autonomous reasoning or autonomous agency, whether the human being was regarded primarily as the possessor of rationality or the bearer of inalienable rights, throughout early modernity and the Enlightenment interest was primarily directed to the human self as such—the rights were typically predicated as universal rights of ‘man’ as such—and the notion of the person began to look inextricably entangled with the particularism of estates and the privileges of the order of ranks typical of the absolutist monarchies. As Hannah Arendt (*Marshall, Alfred (1842–1924)*) has pointed out, the French revolutionaries had no place for the notion of the person, nor thought much of the legal person as a category protected by the rule of law.

A new reversal of the connotations of these two terms takes place in the twentieth century, when the term ‘person’ becomes synonymous with a *non-atomistic* view of the human self. The thick web of relations of recognition that supposedly constitute the person is now understood, within as diverse philosophical traditions as existentialism, Mounier’s personalism or Habermas’s intersubjective view of subjectivity, as a powerful alternative to the modern atomistic self. This motif is at work in John Rawls’s influential ‘political conception of the person’ as endowed with two moral powers, namely the capacity to have a sense of justice and the capacity to form a conception of the good.

2. The Challenges of Conceiving Person and Self

Aside from the issue of their reciprocal relation and their specific difference, ‘person’ and ‘self’ refer to a single human being considered under the aspect of his or her distinctively human capacities. Here we immediately reach a point where the overlap between different conceptions ends and a host of problems arises to which different solutions are offered, which distribute without a clear pattern across the usage of the two terms.

2.1 Identity over Time

The first issue on which different conceptions of the self and the person diverge concerns identity over time. What allows us to consider a person or self that obviously undergoes continuous changes over time still ‘the same person’? In what sense as 50-year-olds are we still the same person as the 20-year-old of decades ago? We can contrast four different answers to

this question. The first answer, typical of ancient and medieval philosophy, links identity over time with the sameness of a (differently conceived) essence—a personal essence underlying also the body—which manifests itself through the changes undergone by the person or self (Plato, Aristotle (*Fisher, Irving (1867–1947)*), Augustine, Aquinas).

The second position connects identity with the psychological continuity of its possessor: it is *memory* and not the physical continuity of the body that allows us to consider the person of 50 years the same as the 20-year-old she/he once was (Locke). The third answer is that of Hume and Parfit: psychological continuity is largely an illusory attribution of an identity, on the part of a mental agency, to episodes that only in a vague sense are similar and related. The self or the person, so conceived, is indeed a gallery of selves and persons whose relatedness is quite tenuous and precariously maintained in the way habits and customs are maintained. By the end of the nineteenth century, Nietzsche (*Helmholtz, Hermann Ludwig Ferdinand von (1821–94)*) gives another twist to the same line of reasoning: we seek to put a construction of unity upon the diversity of our self-experiences for the sake of feeling secure and reassured. Finally, Kant’s (*Quetelet, Adolphe (1796–1874)*) answer transforms identity into a transcendental feature inherent in all human beings.

2.2 Self-consciousness: Inborn Capacity or Product of Socialization and Recognition?

Another bone of contention has been the nature and scope of that capacity for self-reflectiveness and self-consciousness that traditionally all conceptions of the self and of the person have presupposed. The various conceptions have polarized around two major options. One view takes this capacity for self-awareness as a sort of natural endowment of the human being. Either because they belong to her or his essence, or because they are given to her or him as a potential of the soul, or because they emerge as a result of neurobiological processes, self-awareness and self-consciousness constitute an inborn capacity that needs the world only as a sounding board on which the person or self tries out self-initiated action-projects and, in so doing, becomes aware of herself/himself as a center of agency. This view comes in many versions. Augustine and Descartes and Husserl (*Bernard, Jessie (1903–96)*), under different premises, all favor introspection as a privileged path to inner reality. Others, like Hume and Nietzsche, are much more skeptical about it, but all these authors share a view of the self as basically self-sufficient.

The other view starts from the assumption that the capacity for self-awareness is formed in the context of the person’s or self’s relation to the social world. Hegel and Mead, from very different premises, do converge on the idea that self-sufficiency of the self vis-à-vis the

world is largely an illusion, but in fact the self-awareness distinctive of personhood and selfhood emerges in the process of interacting with other persons and selves as a product of either seeking and obtaining recognition (Hegel) or learning to see oneself through the eyes of the other (Mead). From Mead's perspective, thinking becomes a special case of the activity of carrying out a conversation mediated by symbols with others: indeed, thought is best conceived as a conversation with one's own self. From a quite different angle, in his thoughts on the impossibility of a private language and on the notion following a rule, also Wittgenstein (Marr, David (1945–80)) emphasizes the dependency of individuality and subjectivity on shared practices.

This divide is reproduced in almost all social sciences. Within the sociological tradition, for example, theorists such as Spencer Pareto (*Robinson, Joan* (1903–83)), Homans, Blau understand the self of the social actor as coming to the scene of social interaction with a preformed rational capacity for reflection, whereas not just Mead and Cooley, but also theorists such as Durkheim (*Lashley, Karl Spencer* (1890–1958)), Schutz and Parsons (*Simmel, Georg* (1858–1918)) do understand that capacity for reflection as the inner sedimentation of processes of interaction. Within the psychoanalytic tradition, to take another example, theorists like Freud (*Foucault, Michel* (1926–84)) and Klein (*Olson, Mancur* (1932–98)) understand the capacity for ego-strength and rational self-awareness as the product of internal vicissitudes of the drives, while object-relations theorists such as Winnicott or self-psychologists like Kohut understand it as the product of the self's embedment in a relation with an empathic caretaker.

2.3 A Unified Source of Agency or a Decentered Field of Forces?

These considerations lead to yet another major issue with respect to which theories of the person and of the self have taken sides. Some of these theories tend to portray the person as a more or less unified source of autonomous initiatives. Certainly what we call a person or a self contains several distinct aspects—cognition, beliefs, desires, propensities, dispositions, capacities, virtues, etc.—but the views of authors like Plato, Aristotle, Augustine, Aquinas, Descartes, Hobbes, Locke, Kant, Hegel, Sartre, who we find otherwise disagreeing on other aspects, converge in depicting these aspects as being somehow hierarchically subjected to a central agency of sorts. The soul, reason, the will, self-consciousness, are all different ways in which this central agency has been identified. On the other hand, authors again as diverse as Hume, Diderot, Schopenhauer, Nietzsche, Freud, Bataille, Foucault, Goffman, Rorty, Barthes, and Deleuze all share the suspicion that this impression of centered-

ness is largely illusory and the product of impersonal or intrapersonal forces that create it and make it a compelling appearance for the person.

2.4 Continuity and Radical Discontinuity Between Persons and Animals or Machines

But what is it for a being to be a person or self, and what kind of entity can be called a person or a self? Here the opposition is between conceptions that radically sever personhood or selfhood from non-human forms of consciousness and conceptions that take a more nuanced view of the matter, and depict the difference in terms of a gradient of capacities. Starting from the latter, typically we find here conceptions of the person or the self that posit the capacity for representing the world, in order then to act on it, as the crucial defining ability. Humans are then singled out from the rest of beings by self-representation or self-consciousness—which belongs to them alone—but that capacity in turn is only a reflective enhancement of a representational capacity which, as such, can be found also, though to a lesser degree, in certain animal species and in advanced Artificial Intelligence machines. Over limited territories—for example, the kind of representational and practical competence involved in playing chess—machines can even outdo humans. The conceptions which introduce a more radical discontinuity between humans and nonhumans define the former basically as 'subjects of significance' (Taylor, Heidegger)—beings for whom things matter. From their point of view, what distinguishes persons and selves from other beings capable of representation is not just a greater share of 'strategic power,' 'the capacity to deal with the same matter of concern more effectively' or a superior capacity for planning (Taylor 1985, p. 104). The central defining feature is responsiveness, openness to certain strong evaluations, principles or values in the light of which not only single life plans but even one's own life are conceived and assessed. From this standpoint the sense of the self is the sense of where one stands in relation to this matrix of meaning. In one of its most famous versions, this view posits that as persons or selves, human beings are beings for whom their own being is matter of concern (Heidegger).

2.5 The Person, the Self and Fulfilment

Finally, conceptions of the person and of the self do take quite different views of what it means for a person or a self to flourish or to attain self-realization. Some conceptions understand self-realization as being primarily linked with breaking free from the constrictions of an entrenched social order. For example, some authors affiliated to aesthetic modernism (Baudelaire) or to *Lebensphilosophie* (notably Nietzsche) tend to

understand authenticity as something to be attained in opposition to the demands of society and of culture, whereas in the writings of authors such as Rousseau (*Evans-Pritchard, Sir Edward E (1902–73)*), Schiller, Herder, Kierkegaard, and others we find a recognition (with very different degrees of awareness and explicitness) of the fact that social expectations, roles, and institutions cannot be understood as playing a merely constraining, ‘disciplinary,’ or repressive role but also somehow constitute the symbolic material out of which fulfillment can be generated. In the psychological realm, too, we find representatives of these two versions of self-realization. Laing’s understanding of schizophrenia as a response to the imposition of an inauthentic life and of ‘madness’ as resistance to the irremediation of mental life, or Lacan’s understanding of the unconscious, are views of the first kind. On the other hand Kohut’s psychology of the self and Winnicott’s notions of ‘creative living’ and of the ‘true self’ are the most obvious representatives of an integrative understanding of fulfillment within the psychoanalytic tradition.

From another point of view we can contrast coherence-oriented and decentered views of fulfillment. Far from considering fulfilled a life course which can be summed up as a coherent narrative, some consider *narratability* as the epitome of failure. In his reflections on the notion of ‘limit-experience,’ for example, Foucault, continuing a tradition which he associates with the names of Nietzsche and Bataille, equates the paradigmatic kind of fulfilled subjectivity with the one undergoing a limit-experience i.e. an experience in which the self comes close to disintegration. From a variety of *lebensphilosophisch*, aesthetic modernist, poststructuralist, therapeutic, and post-modernist vocabularies, the advocates of a decentered understanding of fulfillment oppose all attempts to restore an internal hierarchy between what is central and what is peripheral to a life-project, a personality, an identity. By contrast, all authors who propound a centered notion of authenticity do wish (a) to maintain some kind of orderly stratification of the layers of an identity, (b) to continue to speak of a core and a periphery, and (c) to make sense of the plurality of experiences, detours, and side-narratives to a life history as variations on a unique theme.

Finally, we can contrast consequentialist and exemplary views of fulfillment. According to the former (what Ronald Dworkin has called the ‘model of impact’), a person’s life is more fulfilling the greater its impact on the external world, the larger the difference it has made. Hegel and Marx certainly share such a view. According to the exemplary view (also called by Dworkin the ‘model of challenge’) the measure of fulfillment is provided by success in meeting a challenge that carries a unique significance for the person, independently of the impact of such success on the external world. Rousseau and Kierkegaard offer representative versions of such a view.

3. Concluding Remarks

To conclude this review of the ways in which the person and the self have been conceived, there could not be a sillier question to raise than ‘Which of these views comes closest to grasping the reality of the human self or the person?’ For these views are in a way not to be understood as representations of an independent reality in the empiricist sense of the word. Rather, they are to be seen as competing vocabularies, as alternative types of lenses—indeed, as sets of premises—which we use in order to make sense of something so crucial for our experience of the world as the idea of personhood. Evidence for and against each of them can be and certainly is usually considered, but is unlikely to be ultimately decisive. Ultimately decisive has generally been our sense of the contribution that adopting one or the other can give to shaping an overall view of the world in which we find reflected what most matters to us.

Person Perception, Accuracy of

The *accuracy* of person perception (also called *personality judgment*) refers to the connection between judgments people make of the psychological attributes of others, and the actual status of those attributes in

the persons who are judged. The psychological attributes may be another person's personality traits, or his or her thoughts and feelings at a given moment. The ability to judge personality has concerned psychological researchers, off and on, for more than a half-century (see Allport 1937, Funder 1999, Kenny 1994). The ability to guess what someone is thinking and feeling, called *empathic accuracy*, is a newer topic that has begun to receive increasing attention (Ickes 1997). Research on either topic entails special difficulties because the notion of 'accuracy' raises thorny questions concerning how accuracy is to be conceptualized and evaluated. Despite these difficulties, research since 1980 can report important empirical and theoretical progress.

1. The Importance of Accuracy

The accuracy of person perception has obvious practical importance. Employers and other people in everyday life rely heavily on their perceptions of other persons' attributes such as conscientiousness, intelligence, friendliness, dominance, and many others. It is an everyday occurrence to make decisions concerning other people as a function of beliefs about what those people are like. Moreover, clinical assessment typically relies heavily on the impressions of a psychiatrist or psychologist concerning a person of interest. Interpersonal judgments and sociometric ratings are also often used as data for psychological research. The accuracy of these perceptions is critical for the quality of the data and the research that is based on them.

The accuracy of personality judgment is also important for theoretical reasons. Accurate person perception implies knowledge about the connections between observable behaviors, on the one hand, and personality traits, on the other hand. Thus, to understand the accuracy of person perception would be to understand the ways in which personality affects behavior. Person perception is a traditional topic of social psychology (see *Social psychology*) and the connections between personality and behavior are traditionally studied by personality psychology (see *Personality psychology*). The topic of accuracy in person perception transcends the boundaries between these traditionally separate sub-fields of research.

Finally, the oldest topic in philosophy, and one of humankind's most ancient concerns, is the relationship between perception and reality. Research on the accuracy of person perception is driven by curiosity concerning just this issue.

2. Difficulties in Accuracy Research

In the light of the importance of the accuracy of person perception, it may be surprising to learn that researchers have neglected the topic for long periods of time (e.g., the years 1955–85), and some psychologists

with relevant interests (e.g., in person perception) continue to shy away. This avoidance has been caused by several considerations. The most important consideration is the topic's inherent difficulty. At a general level, the topic of accuracy is difficult to conceptualize or to operationalize, because it requires the development of some criterion by which interpersonal judgments can be evaluated as right or wrong. Some psychologists have considered the development of such criteria to be either impossibly difficult or in principle impossible, and therefore turned their attention to other topics. At a more specific level, an important series of articles by Lee Cronbach (e.g., 1955) revealed complex and hitherto-unsuspected technical difficulties inherent in evaluating accuracy in terms of agreement among different judges. Rather than leading to improved methods, this article and related critiques managed to shut down a then-lively field of research, and appeared to intimidate a subsequent generation of researchers from addressing the topic (see Funder 1999). A further obstacle to accuracy research was the widespread influence of a set of attitudes that seemed to discourage interest in the topic. The 'person situation debate' in personality psychology (Kenrick and Funder 1988) led many researchers to believe that the connections between personality and behavior were few and weak. If this were true, it would make little sense to attempt to investigate the accuracy of person perception. At about the same time, the increasing popularity of research on 'errors' in person perception (e.g., Nisbett and Ross 1980) led to a widespread belief that human judgment is characteristically, even fundamentally mistaken. If this were true, investigations of accuracy would seem to hold little hope.

3. Resolving the Difficulties in Accuracy Research

Research on accuracy was able to move forward only after these difficulties began to be resolved.

First, views concerning the existence and importance of personality traits, and the abilities of human judgment, began to change during the 1980s. The person situation debate was resolved as reiterating the importance of stable attributes of personality (Kenrick and Funder 1988). Research on the errors of human judgment was reinterpreted in a broader context in which it was less often seen as implying that human judgment is always or fundamentally wrong (e.g., Swann 1984). Studies of error identify important shortcuts ('heuristics') and other processes of human cognition. However, they do not imply that judgment is inept, because the processes that produce errors in the laboratory often lead to correct judgments in real life. Moreover, research on error is fundamentally limited because it can illuminate only how judgments fail to achieve perfection, rather than how correct judgments are ever achieved. The methodological

issues identified by Cronbach and others also received a reexamination during the 1980s (e.g., Funder 1980, Kenny 1994). This reexamination yielded more sophisticated analytic techniques that allowed the methodological complications to be bypassed or specifically incorporated into analytic designs. David Kenny's 'Social Relations Model,' a data-analytic technique that accounts for effects of judge, target, and their interaction on interjudge agreement, was an important breakthrough in this regard.

Notwithstanding the issues just summarized, the thorniest issue in accuracy research is the criterion problem. By what standard can a judgment of personality be evaluated as right or wrong? The answer to this question depends on exactly how accuracy is conceptualized.

4. Conceptualizations of Accuracy

The accuracy of person perception is conceptualized somewhat differently by three major approaches that developed during the 1980s and 1990s.

The *pragmatic* approach, based on some early ideas by William James, has been espoused by William Swann (1984). This approach defines accuracy as the ability to make judgments that allow for success in life. The index of whether a judgment is accurate, in this view, is whether it is adaptively useful.

The *constructivist* approach, based on postmodernist viewpoints that have become widespread in academia, has been espoused by Arie Kruglanski (1989) and others. This approach either states or implies that no criterion for a person's judgmental accuracy exists beyond other judgments by other people. For example, Kenny (1994) has sometimes conceptualized accuracy as the mean judgment of all possible observers of a person. The index of whether a judgment is accurate, in this view, is whether it agrees with the judgments of others.

The *realistic* approach is consistent with the writings of Egon Brunswik (1956) and has been espoused more recently by Funder (1995). This approach assumes that psychological attributes of people really exist, though they are only probabilistically knowable through cues of uncertain validity. The real nature of a person must then be ascertained, as well as possible but always with less-than-certain validity, through multiple sources of evidence including the person's self-judgment, judgments by others, and his or her relevant behavior. The index of whether a judgment is accurate, in this view, is the degree to which it converges with these multiple criteria.

5. The Degree of Accuracy

When research on accuracy in person perception revived during the early 1980s, one of its first orders of business was to dispel the impression left by research

on error, that human social judgment is always or fundamentally mistaken.

A large number of studies documented the accuracy of personality judgment in two ways. The most common method was to show that different judgments of the same person tend to agree. Research examined self-other agreement and agreement among judges and found that significant agreement was the rule rather than the exception across a wide band of personality traits, even after brief periods of acquaintance (e.g., Borkenau and Liebler 1992). Evidence concerning the ability of personality judgments to predict behavior is more difficult to gather and therefore was slower in coming, but eventually showed that layperson's personality judgments have an impressive ability to predict independent observations of an individual's behavior (Funder 1999).

The overall degree of accuracy in person perception is difficult to characterize, because it depends upon a number of factors including the ability of the judge, the judgability of the target, the trait that is judged, and the amount and kind of acquaintance between target and judge (see next section). But while it is for these reasons an oversimplification, it is also a fair characterization to state that the usual correlation among criteria for accuracy is in the range 0.30–0.40. This translates to the statement that one person's perception of the personality of another is correct roughly two times out of three.

6. Moderators of Accuracy

Research since 1980 has found that the degree of accuracy in person perception depends upon four moderator variables.

6.1 The Good Judge

The search for the 'good judge of personality' is one of the oldest concerns in the accuracy literature. This search motivated many investigators during the 1930s to 1950s and it was their failure to find consistent results that contributed to the three-decade hiatus that followed (Schneider et al. 1979). Part of the reason for this failure may be the presence of methodological flaws in many early studies, and another part may be that judgmental ability may not be robust. That is, a good judge of one kind of person or trait may not be a good judge of other people, other traits, or in other contexts. Research continues to address this topic but at present the 'good judge' has yet to be conclusively found.

6.2 The Good Target

The search for the good target of judgment, or the 'judgable' person, has had more success. As Gordon

Allport noted years ago, some people are relatively open books whereas others are difficult to understand even after years of acquaintance. According to research by Colvin (1993), the judgable person is one who has an integrated, well-adjusted personality. The consistency among such a person's actions, thoughts, and personality leads them to be coherent overall, and relatively easy to judge.

6.3 The Good Trait

An even more robust phenomenon is the difference among traits in their judgability. Relatively observable traits, like sociability and talkativeness, are much easier to judge accurately than more hidden traits like ruminativeness and anxiety. Some evidence also suggests that traits that are extremely desirable or undesirable to possess are more difficult to judge accurately than traits more neutral in evaluative connotation.

6.4 Information

The accuracy of a judgment also depends critically upon the information upon which it is based. The information variable has two facets, quantity and quality.

The quantity variable pertains to the *acquaintance effect*, the tendency to judge someone more accurately the longer one has known him or her. The straightforward expectation would be that more information is likely to produce more accurate judgment. Perhaps surprisingly, this has turned out to be a controversial proposition, with some investigators finding evidence for the acquaintance effect, and others doubting its existence on theoretical and empirical grounds.

The quality variable pertains to the kind of context in which one person observes another. Current research is pursuing the idea that, even holding amount of acquaintance constant, different contexts may produce different degrees of accuracy.

7. Theoretical Development

Historically, research on accuracy has been long on empiricism and short on theory. This imbalance is beginning to be remedied with the development of theories of how accurate judgments come about. One theory, Kenny's 'PERSON' model, conceptualizes personality judgments as the result of multiple influences including the judge's response proclivities, his or her knowledge of people in general, the actual personality of the target, and other factors. Another theory is Funder's Realistic Accuracy Model (RAM, Funder 1995). RAM conceptualizes an accurate personality judgment as the result of a process that begins

with the target emitting relevant information (e.g., performing a relevant behavior), which then must become available to a judge, who then detects it and utilizes it correctly in reaching an accurate judgment. Both the PERSON and RAM models can be used to rationalize the moderators of accuracy that have been found to date, and suggest new ones for investigation in future research.

8. Conclusion

The accuracy of person perception is an important topic that, after periods of neglect, is becoming a mature field of research and a mainstream concern of personality and social psychology. The combination of empirical and theoretical progress in this area makes it a good candidate for becoming even more central within psychology in the twenty-first century.

Personal Identity: Philosophical Aspects

1. Personal Identity: a Modern Problem

Identity has two meanings: it denotes category membership (e.g., X is a politician); or it identifies a specific individual (e.g., X is Mr. A). Goffman (1963) speaks of social and personal identity. Different criteria are used to determine both types of identity: physical criteria (e.g., sex, race, a thumbprint, a conspicuous scar); social criteria (e.g., general roles such as teacher, or judge, and unique roles such as queen of England or pope); and psychological criteria (competencies or personality characteristics as general variables, and unique values in any of these variables, such as the world's best tennis player).

In traditional societies, all of these criteria converge when they are used to classify individuals. They converge across contexts, across the life cycle, and across perspectives. To illustrate, the identification of X as 'tenant of the Z farm' simultaneously ascribes a social identity (e.g. X is a man, a farmer) and denotes personal identity (i.e., X is the stout, pockmarked man living at the south end of the village, who keeps initiating political debates in the pub). The identity markers used are valid in all contexts: in his family, in the village, in the pub everybody will know him as the pockmarked man running farm Z. They are valid across his life-span: From birth to death he is linked to the Z farm as its future, present, or former tenant. And descriptions from first- and third-person perspectives agree: his farmhands, his wife, and the other villagers know him as the tenant of Z, and he also identifies himself with this attribution—in fact so much so that he will have written on his tombstone: 'Here lies the tenant of Z farm.'

With modernization these dimensions diverge. As a result of urbanization, social and personal identities separate: town people can only vaguely guess each other's social identity, let alone know their personal identity. Social differentiation and cultural pluralization produce consistency problems: individuals increasingly partake in several subsystems or subcultures, each operating according to their own code or claiming specific value commitments. Thus, in different contexts they find themselves exposed to specific role expectations which quite often make conflicting demands. Rapid social change impedes the experience of personal continuity over the life course (e.g., elderly Germans have been subjects in an empire, citizens in the Weimar Republic, followers in a totalitarian regime, and citizens in a democracy again).

In general, modern sociostructural arrangements contribute less to the establishment and stabilization of identity than those of the past. From a third-person or a societal perspective, this is unproblematic. Members of modern societies are used to acknowledging or ignoring each other as strangers. When someone's

identity needs to be known there are social mechanisms for identification: titles, uniforms, or the office reception area inform on status or social identity; a passport or genetic analysis enable us to determine personal identity; the curriculum vitae and certificates give evidence of personal continuity; institutionalized sanctions guarantee at least context-specific consistency. A problem does, however, arise from a first-person or internal perspective. The question 'Who am I?' is not satisfactorily answered by referring to unparalleled fingerprints or to social positions held. Rather, individuals are in need of a sense of uniqueness, and a feeling of inner consistency and continuity over and beyond matchless physical markers or straight careers.

2. Theoretical Solutions to the Identity Problem

Various solutions to this modern problem of a subjective sense of identity have been proposed. In some of his writings Erikson (1958) assumed identity to be grounded in those lifelong substantive commitments (to a partner, an occupation, a worldview) a person enters upon, having successfully solved the adolescence crisis. Nowadays, however, people keep experiencing ever new crises (e.g., midlife crises, retirement crises, etc.) in which such commitments are revoked (e.g., by divorce, religious or ideological conversions, loss of employment, or occupational changes).

Elsewhere, Erikson (1956) defined ego identity as a formal competence: the competence to uphold internal unity and continuity. This competence arises from successful resolutions of previous crises in which basic trust, autonomy, initiative, and a sense of achievement (rather than distrust, shame, doubt, and guilt, and a feeling of inferiority) have been developed. In this definition, however, people's need for substantive commitments remains unfocused.

Krappmann (1969) sees identity arising from the social recognition found in those interactions in which an individual succeeds in balancing out contradictory expectations, while at the same time signaling that they never will be merged totally in any given context. Krappmann, however, fails to specify any criteria that might enable us to distinguish opportunistic forms of balancing from the principled type of flexibility that is a prerequisite for warranting an inner sense of consistency and continuity.

Postmodern approaches deny that identity may need consistency and continuity. Instead, they propose the concept of patchwork identity to reflect the fact that there are constant changes in preferences, attitudes, roles, and relationships. However, even the external criteria that might enable us to distinguish one patchwork from the other, or to recognize sameness over time in case individual patches have been exchanged or colored, remain unclear. And from

an internal perspective, body boundaries and physical continuity are not enough to confer a sense of identity. In fact—as is well documented by research in various fields such as dissonance theory, attribution theory, and studies on dogmatism and split personality—at least some consistency seems indispensable for psychological well-being and mental health.

Cohen and Taylor (1976) focus on sense of uniqueness. Individuals seek to develop eccentric hobbies, interests, or life-styles, go in quest of adventure or unusual experiences so as to resist the fear of exchangeability that keeps creeping up on them in modern mass societies. Nevertheless, over and over again, they find that any newly invented identity marker will be imitated by others, socially co-opted, and commercialized. Thus, all attempts to secure personal identity by appropriating singular activities are—empirically—doomed to failure. Moreover, the very idea of basing identity on unique markers is misconceived because it reduces the dialectic inherent in distinctiveness to just one pole—to positively valued exceptionality—and overlooks the risk of being seen as deviant and becoming stigmatized. More importantly still, it neglects the core feature of a sense of uniqueness—its being a ‘necessary byproduct’ (Elster 1979). There are states such as sleeping, forgetting, or happiness that will inevitably be missed by those who directly aim for them. In the same way, a sense of uniqueness can only be experienced concomitantly; i.e., as a consequence of doing something one is intrinsically committed to doing.

Giddens (1991) conceptualizes identity as a ‘consistent narrative’: enveloped in the ‘protective cocoon’ of basic trust, individuals keep rewriting their autobiography so as to create a consistent meaning structure from the sequence of decisions made, the paths chosen, and the actions taken. This definition integrates motivational aspects (trust), substantive commitments (life decisions), and a need for consistency. The meaning of consistency, however, remains ambiguous: by insisting that identity be based on a ‘morality of authenticity that skirts any universal moral criteria’ (Giddens 1991, p. 79), Giddens cannot distinguish between consistency based on principles or consistency based on defensive rationalizations (‘sour grapes’).

3. Aspects of Identity: Theoretical Assumptions

From this brief overview and critical comments, several assumptions concerning constitutive aspects of identity can be derived:

- (a) Commitment is constitutive of identity.
- (b) Given that commitment needs an object (e.g., a person, values, projects), content is requisite for identity.
- (c) What matters, however, is not the type of content chosen, but the mode of appropriating it.

(d) A subjective sense of uniqueness is a necessary by-product of an autonomous commitment.

In the following, these assumptions will first be theoretically justified. Second, I will try to substantiate them empirically.

Assumption (a) follows Frankfurt’s (1988, 1993) analysis of the concept of a person. If an individual had nothing he/she would never betray, he/she would be at the helpless mercy of contingent conditions, of inner drives, of fleeting whims. He/she would not be a person but a ‘wanton’. Personhood (i.e., identity) is acquired by committing oneself to ideals. The kind of ideals chosen—be they moral, aesthetic, or truth-oriented ones—is of little import. What counts is that the person—in view of his/her commitment to an ideal—is taking a stance toward spontaneous impulses and desires, and is suppressing those that are incompatible.

Frankfurt describes the way in which identity is constituted; Nozick (1981) analyzes the way in which it may be stabilized. He proposes the following thought experiments. Assume that Theseus’ ship is anchored in port. As time passes, one plank after another is beginning to rot and is replaced. Finally, all the planks have been replaced by new ones. What is Theseus’ ship? The renovated ship in port or the original planks piled up in the shipyard? We would consider the ship in port to be Theseus’ ship, because, despite a change in its components, it has maintained its structure and its transformation is of some continuity underneath the seties. Analogously, we consider an organism to continue to be itself despite the fact that its cells are continuously replaced. Similarly, we consider a person to remain the same even if they have changed some of their views. We do so only, however, if we assume that they have changed their views autonomously, i.e., voluntarily, and with good reason. Nozick explicates this using counterexamples. Assume that, due to grave brain damage, a man has been suddenly reduced to the state of an infant, or that as a result of brainwashing, an ardent democrat has been transformed into a fanatic communist. We would say of both that they are no longer the people they once were. In contrast, we have no problem in acknowledging the identity of a former opponent to atomic energy who is now arguing *for* the use of atomic energy, if we can understand this change of mind as being motivated by reasons (e.g., a fear of global warming), and not effected by causes. In other words, we do not consider identity to be endangered if changes in mind result from learning processes. The concept ‘learning process’ implies that the new state is better than the former; i.e., it presupposes intersubjectively validated standards to judge the adequacy of views held. Unavoidably, everyday life is based on such collectively shared understandings of rationality—otherwise the very idea of, for example, questioning the identity of the brainwashed communist would be meaningless.

4. Aspects of Identity: Some Empirical Support

There are empirical findings that agree with these philosophical reflections. In *The Uncommitted*, Keniston (1965) describes the feeling of inner void and meaninglessness, and the sense of exchangeability some young Harvard students experienced despite the fact that from an external perspective they were considered as being highly successful; i.e., ascribed a positively valued identity. In contrast, by committing themselves to something they deem worthy and important, the Civil Rights Movement, the *Young Radicals* (Keniston 1968) increasingly came to develop a sense of uniqueness. Similarly, Helen John, a leading pioneer in protests against nuclear missiles, came to feel irreplaceable once she began to accept personal responsibility. As she put it: 'Nobody can do exactly what I am doing, in the way I am doing it. Only I can do that.' (Haste 1993, p. 339) The sense of uniqueness is not dependent on 'difference,' on singular contents; rather, it is dependent on personal commitment. Only in truly caring for something can a person feel inexchangeable.

Individuals tend to realize that caring for specific ideals is constitutive of their own identity. In the context of a longitudinal study I asked 170 17-year-olds: 'What would most make you a different person—different looks, parents, hobbies, grades, a different understanding of right and wrong; another nationality, sex; a lot of money? Why?' The answers given most often were: different parents, different sex, different moral understanding. The importance of 'ideals' to identity could be seen in the frequent references to 'moral understanding,' and in the justifications given for the response 'different parents.' Most subjects argued that growing up in a different family would make them a different person because parents so decisively influence and shape one's value orientations. There is a more indirect confirmation of the claim that ideals are constitutive of identity: many longitudinal studies find that individuals tend to hold on to the sociopolitical value orientations developed in late adolescence—even if they have experienced social and geographic mobility or fluctuations in public opinion (cf. Sears 1981). This finding may indicate that people seek to stabilize their identity during their life course by remaining true to their value commitments—irrespective of changes in context or the ideological climate.

As noted above, however, this mode of upholding identity is rendered increasingly difficult given rapid and far-reaching changes in knowledge systems and collective interpretation. In the following, I maintain that with modernization two new mechanisms that enable us to constitute and stabilize identity are evolving: value generalization and an egosyntonic motive structure. I will illustrate both using data from a cohort comparison involving 100 65- to 80-year-old, 100 40- to 50-year-old, and 100 20- to 30-year-old

subjects representative of the West German population. The study focused on the understanding of moral rules and moral motivation (cf. Nunner-Winkler 2000a, 2000b). In making use of these data in the present context I do not, however, wish to imply that the ideals constitutive for identity need to be moral ones.

5. Mechanisms for Stabilizing Identity in Modernity

5.1 Value Generalization

Commitment to more abstract values increases the flexibility required if varying context conditions are to be taken into account. To give an example: when asked to judge a young mother's desire to work full-time without real economic need, older subjects express clear condemnation; they see it as a neglect of duty. Younger subjects, in contrast, no longer assume ascriptive female duties; they focus on the problem of good child care. On these more abstract terms several functionally equivalent solutions are possible. Similarly, older subjects tend to condemn a sexual relationship between two men as unnatural, deviant, or sick. Younger subjects instead tend to discuss it in terms of the quality of the relationship. Thus, increasingly concrete rules tying behavioral implications to specific context conditions (e.g., child care to being a mother; sexual relations to being of the opposite sex) are replaced by more abstract values (e.g., welfare of the child; quality of the relationship) that allow flexibility in realization without a betrayal of basic commitments.

5.2 Egosyntonic Motive Structure

Norm conformity can be motivated by various concerns: by fear of physical or institutional sanctions, social contempt (Luhmann), or pangs of conscience (Freud); by compassion (Schopenhauer); by respect for the law (Kant). In a longitudinal study on moral development it was found that children see moral behavior as being motivated not by the consequences anticipated either for the wrongdoer or for the victim (e.g., by fear of sanctions or by compassion), but by an intrinsic desire to do what is right (Nunner-Winkler 1999). The cohort comparison shows that between generations there is a change in the understanding of moral motivation indicated by changes in the emotional reactions expected to follow transgressions. Older subjects mostly refer to guilt and shame; that is, to emotions that focus on some higher internal or an external entity (e.g., the superego or a social audience); younger subjects, in contrast, are more likely to express sorrow or regret; that is, emotions that focus on the wrong committed or the harm done. Thus, norm conformity is increasingly coming to be seen not

in terms of bowing to dictates authoritatively imposed on people but rather in terms of not wanting to wrong others. This change in moral motivation in the direction of a more egosyntonic structure corresponds to a change in the cognitive understanding of morality, in as much as norms are no longer seen to be set by God or church authorities, but rather as derived from rational consensus among equals.

To conclude, with modernization—i.e., with social differentiation, cultural pluralization, and rapidly changing social conditions—new mechanisms have evolved that allow us to constitute and stabilize identity. By egosyntonic commitment to generalized values individuals may develop a sense of uniqueness, and experience consistency and continuity in their life course. In this way ego identity becomes a substitute for social role identity.

Personal Privacy: Cultural Concerns

Personal privacy is a vexing and invaluable concept: vexing because it is difficult to describe; invaluable because privacy allows people the possibility of freedom, and thus autonomy and personal choice. In this sense, privacy is a precondition of psychological concepts of identity: the modern ideal of an individual requires—and cannot be fully realized without—substantial privacy. Personal privacy can be pictured as the atmosphere generating part of the ecosystem in which this individual can draw breath.

Perhaps most succinctly defined by the US social philosopher, Sissela Bok (1982), privacy is ‘the condition of being protected from unwanted access by others—either physical access, personal information or attention.’ This protection, whether physical, political, or psychological provides freedom because it shelters people from intrusion; it fends off predators that might pre-empt personal choice; it grants control. Privacy also emphasizes interiority: the subject—while protected from undesired surveillance and intrusive access—is freed to focus more fully on self-observation, and to develop efficacious forms of self-expression.

1. Historical Background

An early template of this phenomenon can be found in Jane Austen’s novel, *Pride and Prejudice*, published in 1813. Midway through the novel, its heroine Elizabeth is sitting alone in a room reading a letter when the romantic hero, Darcy, comes upon her and is startled by her solitude. Modern readers may not recognize what an unusual spectacle such a tableau offered in Austen’s era. Women were rarely alone, and many were only recently literate enough to read and write letters. The book also describes Elizabeth’s startling penchant for solitary walks. Her search for solitude underscores her characterization as a new, independent woman with a more self-conscious and thus a sturdier sensibility. Alone in a room with time and

peace to peruse an intimate letter, Elizabeth can contemplate her reactions to what she is reading. She can notice what she thinks and feels without immediately being distracted or having her impressions overrun or overruled by others around her. Given a pen and paper, she can respond from her own perspective; she can express an opinion, and in a larger sense, a point of view.

These behaviors, made possible by privacy, and the resulting increased capacities for autonomous voice and self-expression, distinguish Elizabeth from her less able peers, and define her as a substantial individual in a modern sense. This view is furthered by her refusal to marry Darcy when he first approaches. Although he is wealthy and upperclass, and she is from a more middle-class family with money worries, and although marriage is the only avenue into society for her, she refuses his offer because she does not love him. Her behavior is radical as it suggests love—and the sensibility of the subject—as a value of more significance than social standing or economic well-being. While in contemporary Western culture, many take for granted love as the superior foundation for marital commitment, this notion, this privileged of private feeling, is also—historically speaking—new, having developed a popular following gradually over the past few centuries. And, as Austen illustrates, in the era of *Pride and Prejudice*, it was easily displaced by other imperatives.

Austen's heroine is only satisfied when she can choose to marry Darcy, based on her private feelings—those she discovers within her heart. Elizabeth's insistence on such a course illustrates well the confluence between forms of privacy, like solitude, and the heightened capacity for personal choice based on feelings. One emphatic version of this idea of individual integrity rooted in private experience was asserted by the US transcendentalist Bronson Alcott (1799–1888) when he wrote, 'Individuals are sacred. The world, the state, the church, and school, all are felons whenever they violate the sanctity of the private heart' (in Seipp 1981, p. 99).

While all cultures have had some notions of privacy (Barrington Moore Jr. 1984 traces its rudimentary presence in Ancient Greece and the Old Testament), the modern concept—illustrated so well in *Pride and Prejudice*—has been developing gradually since around the seventeenth century. The cultural historian Philip Aries (1962) has pointed out that until the early seventeenth century, almost no one in Europe spent time alone. But privacy is more than solitude. Alan Westin defined its four substates as solitude, anonymity, reserve, and intimacy. While these states are diverse, they all describe methods of purposefully shielding oneself from the physical and/or psychological 'gaze' of others.

The ideal of personal privacy is partly an outgrowth of a gradual social transition accompanying the mass urban migration of the nineteenth and twentieth

centuries. People left communal situations—small towns and villages where their lives, monitored by church and neighbor, had been witnessed closely and controlled largely by people who knew them. Finding themselves more alone, separate, and increasingly anonymous, people, first in cities then in suburbs, realized that they were at liberty to choose their activities and behaviors with less reference to communal imperatives. Although in part following an economic infrastructure defined by industrialization and capitalism, this increased autonomy drew its cultural meaning from philosophies of individual rights and freedom. While the sources are too many to site, one would have to acknowledge the influence of John Locke, Edmund Burke, Jean Jacques Rousseau, Johann Goethe, William Wordsworth, Thomas Jefferson, Ralph Waldo Emerson, Mary Wolstencraft, Margaret Fuller, and Henry David Thoreau among many others.

Within this tradition, privacy can be defined as the right to make one's own choices relatively unobserved, unchastised, and unimpinged upon by others—whether individuals or institutions. While there is no legal 'right to privacy' in the USA, the concept began to be articulated in the late nineteenth century. In 1872 the feminist Victoria Woodhull referred to 'the right to privacy' in a newspaper piece. The famous expression, 'the right to be let alone,' was then coined by Judge Thomas Cooley in 1879. In 1890, Samuel Warren and Louis Brandeis published a landmark article, 'The Right to Privacy' in the *Harvard Law Review*. No important discussion of privacy in the USA since then has failed to refer to Warren and Brandeis.

Privacy had been increasingly understood as a precondition for human dignity. Shielded from intrusive observation, people take control over the matter of 'showing' themselves to others or not based upon their own sense of readiness. Few feel dignified when exposed to hostile or secret surveillance. Privacy functions as a practice room in which people can process and master experience before displaying themselves to others. Having this option, people feel less shame. Shame is in essence an internal overseer—employed by those parts of the mind whose job is to keep the individual in line with the communal norm. Privacy provides the space in which the communal demand can be weighed against the internal individual imperative, and a choice of behavior made through consideration rather than reflex. Since shame is also a psychic experience where the sense of self temporarily disintegrates, the shielding of the individual with privacy, the minimizing of shame, and the valuing of dignity, all enforce conditions which enhance people's sense of individual identity and worth.

2. Theories of Privacy

Alan Westin's landmark book, *Privacy and Freedom* (1968), defined four states of privacy. Because these

states are to some degree counterintuitive, it is useful to describe them. The first—solitude—is perhaps the most self-evident and the one most popularly associated with privacy. When privacy is mentioned, the mind often jumps to an image of a person alone, whether in nature or in a room. In US literary culture, one might think of Henry David Thoreau living at Walden Pond, or—half a century earlier—of James Fenimore Cooper's fictional frontiersman, Natty Bumppo, independently making his way through the American wilderness. Solitude is the most complete state of privacy; in it one is physically separate from others. Historically, solitude has been associated with men and linked to images of independence, moral awareness, and strength. Until recently in Western Europe and North America, women were only granted solitude for prayer. Unchosen, solitude becomes isolation and, like the extraordinarily punitive condition of solitary confinement, can be a psychically destructive experience; people, with inadequate access to others become more inclined to psychic turmoil.

Anonymity is Westin's second state of privacy. When one is with others but unknown to them, as in a crowded train or a city or a suburban shopping mall, one is anonymous. Anonymity offers privacy by allowing human proximity in the absence of knowledgeable witnesses. One is freed in this situation (for better and worse) to experience a subjective sense of oneself or of current experience unchallenged by the proximity of knowing and potentially contradicting others. The degree of anonymity that urban and suburban dwellers experience today is historically atypical and sometimes shades into the alienating sense of anomie.

The third state of privacy is reserve. Reserve is perhaps the oldest and most universally available form of privacy; the privacy one can access even when surrounded by intimates. It is the default state of privacy, the great mediator of psychic survival and human freedom. One has, thanks to reserve, the freedom not to say openly or fully what one thinks or feels, not to reveal oneself in situations that feel unsafe. Reserve is a basic element in civility and civilization, but more than that, it negotiates the distances between people, facilitating all varieties of encounter by allowing exchanges among people where disruptive observations go unspoken and social intercourse is expedited. It is also one of the equalizers in social power. The powerful, denied critical response or information by the reserve of the 'weak,' can have their intentions impeded.

Intimacy is Westin's fourth state of privacy, and perhaps the most surprising one to find in association with the others. Intimacy is a state of privacy where two people, or a small group or a family, shielded from the larger group, are able to reveal themselves more fully, physically, psychologically, sexually, and so forth. As individuals have come to live more separately and less communally, there has been an increased

demand for intimacy in primary relationships. At the same time, continuing our delineation of the relationship of privacy to the ideal of the more fully developed individual, intimacy is considered a well-spring for psychic development. Within intimate relationships, individuals hope to find validation of their nascent self-expression which then ideally strengthens and reinforces their capacity to carry that private self into the public world. Intimacy also provides release in the form of freer emotional and sexual expression.

The 'possibility' within privacy also includes individual artistic expression, which in turn dovetails with the romantic emphasis on the artist as the highest realization of modern sensibility. According to this view, well articulated in Charles Taylor's (1989) compendium on the sources of modern identity, the artist, creating in private and using privacy to appropriately shield and nurture his or her creative process, expresses otherwise obscured, often internally uncovered, truths about human experience, and by so doing transforms that experience.

And while the artist may be the prototype of this style of individual, it would be a mistake to minimize privacy's broader but related function in everyday life. Take two contemporary flashpoints as illustrative: One can see the critical role of personal privacy both in the abortion debate and the gay rights movement. In both these situations, the wish of individuals to choose behavior around sexuality and procreation is placed in conflict with traditional social imperatives. Specifically, these imperatives have dictated the primacy of procreation and heterosexual procreative sex. In both cases, the progressive position has been framed as valuing individual choice above procreation specifically because this choice highly values subjective experience—the primacy of the individual heart. Thus the individual's private feelings—about readiness to have children, or the number of children to have, about whom one wants to love and how—are held to be of worth precisely because they enforce people's capacity to act according to their own lights, and to transform themselves by these actions: to become 'more fully' human through freedom.

Sigmund Freud's notions of a complex human psychology that requires and transforms itself through self-knowledge, and particularly through self-knowledge inculcated in the intimate process of psychoanalysis, fits within this modern template. In the various psychotherapies which have proliferated in the USA and Europe during the twentieth century, the therapist assists patients to become themselves more fully by verbalizing their private (even secret) heretofore inexpressible thoughts and feelings. The process of naming, the intimate yet contractual relationship, and the resulting restructuring of aspects of the patient's mind are meant to create a transformative and relatively liberating self-knowledge. The privacy of the consulting room and the confidentiality of the process are considered central to its efficacy in that

they secure a free space between social demand and individual subjectivity.

3. Threats to Privacy

Privacy is a fragile state, and one—as the twentieth century has demonstrated—that is exploited readily. No discussion of the merits of personal privacy can be complete without some exploration of its accompanying liabilities. While many of the most eloquent voices of the twentieth century—among them George Orwell, Nadia Mandelstam, and Primo Levi—have delineated the damage to liberty and individual authority brought about by hostile surveillance and its companion, terror, less has been said until recently of the equal threat to privacy caused by secrecy and social isolation. (Perhaps the one historically illuminated aspect has been in those instances when it has been tied with totalitarian power wherein the masses are placed under surveillance while the motives and behaviors of leaders are kept secret.)

But domestic secrecy turns out to be a potent destructive force with regard to personal privacy. Under the guise of privacy, more powerful members of families have had reign to exploit or abuse less powerful members—whether emotionally, sexually, or physically. These acts are significant not only because of their exploitative dimensions, but because by their very nature they stunt the freedom of the oppressed to use the privacy for the aims elaborated above. Any historical survey of social conditions would suggest that such abuse has always been amply present. Yet what has altered currently may be an ideology which pictures family life as unrealistically benign—‘a haven in a heartless world’ (Lasch 1977)—an idealization that sometimes denies, sometime mitigates, the inherent violence.

A corollary concern is the degree to which many of the benefits made possible by personal privacy accrue only to a privileged or powerful few. Does such a scatter imply that privacy reinforces other social hierarchies, or can it still be construed as a valuable humanistic ideal which will only find full expression if social justice increases other aspects of social equality?

So too, US social philosophers like Christopher Lasch, and the ‘communitarians’ Robert Bellah and Amatai Etzioni have attacked aspects of US individualism which they see both as excessive, and as indulging an unchallenged pursuit of private purpose and private gain at the expense of the welfare of a larger group. According to this critique, the goals of the individual and the community may be enough at odds to warrant more vigorous interventions on the part of the state to protect communities. Privacy becomes implicated in this debate for its functions shielding individuals and honoring their imperatives.

The technological revolution of the present age also threatens privacy. Computer databanks, video

cameras, audio taping, sophisticated surveillance capabilities, and medical technologies like DNA testing make it extremely easy for people to learn private information about other people which was more difficult to access earlier in the twentieth century. Reacting to excessive social isolation and anonymity, and to the enormous profit in selling private information, there is strong interest from many quarters in developing new ways of observing others. The technological gains have come so quickly that inadequate attention is being paid to their pros and cons with regard to the value of preserving privacy. So, for example, the DNA sampling in prison of a petty offender implies a lifelong increased access to knowledge about that individual by the state. And civil liberties issues have tended to get suppressed in the enthusiasm for the new capabilities.

4. Conclusion

In summary, personal privacy protects a wide variety of modern social ideals. Privacy advocates argue that people have a right to be ‘let alone’; and that, shielded from excessive authoritarian intrusions, people will make choices based on some more personal sense of what is desirable, that thus constitutes more authentic self-expression. As a corollary, these ideals justify and affirm other cultural notions which support individual liberty and dignity, the value of self-knowledge, and they privilege relationships based in love.

Personality and Adaptive Behaviors

Personality is the psychological system that mediates the relationship of the individual with the environment in the service of adaptation. It is the complexity of structures, processes and patterns of affect, cognition and behavior that we call 'personality' that conveys to others the sense of unity and distinctiveness that distinguish individuals from one another and that grants to each individual a sense of identity, of wholeness and uniqueness.

Because the term encompasses a great variety of phenomena it is not surprising that different ideas appear in various combinations in the traditional and common usage of the word personality: human being, person, the quality of being a person, the quality or fact of being a particular person, patterns of habits and qualities of any individual as expressed through physical and mental activities, the sum of such properties as impressing or likely to impress others, and what makes an individual conspicuously different from others.

Nor is it surprising that, given the complex nature of personality, different assumptions, foci, and strategies of research have marked the study of personality since the beginning of the discipline (Allport 1937, Murray 1938, Stagner 1937, Stern 1935).

The resolution of these different definitions and assumptions has considerable implications for the conceptualization and study of adaptation and adaptive behaviors.

1. Common Assumptions Regarding Personality

Before outlining these different assumptions, let us first consider some areas of commonality in the contemporary field. Most investigators in personality psychology share an 'interactionist view'. In other words, they view personality as an open system that develops and functions through continuous and reciprocal interactions with the environment (Bandura 1986, Hettema 1979, Magnusson and Stattin 1998).

Personality, then, refers to a complexity of psychological structures and processes that operate in concert in these person-situation interactions. The personality system underlies the distinctive patterns of affect, cognition, and behavior that foster coherence in individual conduct and experience over time and across settings. Molar psychological mechanisms, such as the goals, beliefs, and skills through which individuals regulate their experiences and actions, result from the synergism of underlying biological and psychological subsystems. Multiple biological systems, cognitive and affective structures, behavior, and the environment all operate as interacting determinants of what personality is at any moment within a network of reciprocal causation. The relative influence of one or another personality determinant varies in different individuals, and across activities and circumstances. Individual development and functioning are processes of continuous restructuring of the whole system and its subsystems within the boundaries set by biological and social constraints (Caprara and Cervone 2000).

2. Competing Arguments Regarding Personality

Despite the widespread adherence to an interactionist viewpoint, continuing debates in the field attest to the fact that many fundamental issues are still pending, with different investigators adhering to different theoretical and metatheoretical principles and assigning different importance to nature, nurture, or the individual in the shaping of their personalities (Cervone 1991). Throughout much of its history, personality psychology has been concerned with individual differences in observable variations in styles of behavior, affect, and cognition. The variations have been organized according to, and traced back, to simple systems of dispositional constructs.

Dispositional constructs are designed to encompass the variety of phenotypic expressions of individuality and to capture the consistent individual differences that are observed. Trait constructs have been posited to account for stable patterns of experience and action that people exhibit, and that distinguish them from one another. As different traits are differentially relevant to different settings and their expression is differentially sensitive to social contexts, different traits attest to the consistency of personality in various degrees depending upon their generalizability (across individuals), pervasiveness (across situations), and stability (across time). This has led dispositional theorists to conceptualize personality as a hierarchical organization and to focus on high level traits (e.g., extroversion) that organize lower level tendencies (e.g., sociability) which, in turn, supervise lower level behavioral habits (e.g., talkative) (Eysenck 1970).

In the past alternative taxonomies have been in conflict with each other. However significant con-

sensus recently has been reached on the importance of five factors (so called Big Five) that are obtained robustly: Extroversion, Agreeableness, Conscientiousness, Emotional Stability, and Openness to Experience. This five-factor model has become a point of convergence between the psycholexical tradition, mostly concerned with personality description (Goldberg 1993), and the tradition, mostly concerned with the identification of the primary structures of personality (McCrae and Costa 1996).

Significant differences are found among five-factors investigators, who may disagree on the exact nature and conceptual status of the trait variables (see Wiggins 1996). However, far more profound differences separate those who view traits as the ultimate determinants of personality from those who conclude that clustering descriptors related to habitual behaviors (as resulting from factor analysis) cannot lead too far in understanding either the regularities that explain personality functioning or the uniqueness which distinguishes persons from one another (Bandura 1999). The issue in contention is not whether people have personal dispositions, nor their determinative role in personality functioning, but rather how dispositions are conceptualized and operationalized. Dispositions may correspond to habitual styles of behavior rooted in genotypes, or to self-regulatory structures (as internal standards, aspirations and goals, and efficacy beliefs) resulting from the organization of affect, cognition, and behavior which emerges over the course of life.

In conceiving of personality as a hierarchical architecture in which basic traits are at the origins of any other individual disposition or behavior, most convinced advocates of traits as genotypes of personality derive their arguments from genetic, longitudinal, and cross-cultural studies. Genetic studies have found a consistent component of heritability for each of the Big Five (Lohelin 1992), longitudinal studies have shown a significant stability of the same traits over the life span (Costa and McCrae 1997), and cross-cultural studies have shown that the multiple descriptors used to describe personality in different cultures can be traced back to few common dimensions broadly overlapping with the Big Five (De Raad 1998). Trait psychologist converge with evolutionary psychologist in viewing adaptation as largely predetermined by the basic dispositional equipment of the species selected through generations. According to this view adaptive behaviors (in mating, fighting, solving problems, and coping with adversities) largely reflect the influence of evolved mechanisms whose nature and functioning has been determined over the eons through processes of natural selection (Buss 1997).

On the other hand, in conceiving of personality as an open, dynamic, unifying and integrating system, social cognitive and motivational theorists (Cervone and Shoda 1999) point to the emerging properties of the mind and focus on the processes and mechanisms

conducive to knowledge structures which enable personality to function as a proactive self-regulatory system. Thus, they contest the generalizability to individuals of correlational findings derived from studying populations, and thus leaving large portions of variability unexplained. Rather, they focus on the construction of personality as an integrative and coherent system as it takes place over the course of life, on the processes that enable the system to function proactively with the environment and on the structures that orchestrate these processes. Ultimately they emphasize the flow of reciprocal determination among biological, psychological and social factors which sustain the whole construction, and from which the agentic properties of personality derive. In this view of personality, 'adaptation' is eminently relational and contextual. Adaptive behaviors are not ascribed to any preformed, endogenous dispositions, but to psychological systems which themselves develop through dynamic interactions with the social environment. These systems enable the person to cope in a flexible, innovative manner with the diverse challenges of life.

3. Personality as a Self-regulatory System

Personality can be viewed as both a construction and an agentic system. Over time, people gradually construct a sense of self through their interactions with the social world. People's capacity for forethought, performance control, and self-reflection contributes to their ability to regulate their own experiences and actions. Self-regulatory capacities enable people to contribute proactively to the course of their development. Personality, then, reveals itself as a construction endowed with agentic properties. These properties enable people to exert a broad influence on their environment and their own psychological and physical selves (Caprara and Cervone 2000).

Agentic personality functioning involves a number of distinct processes. People select the environments they encounter and thereby create opportunities for themselves, guide their behavior purposively, appraise their circumstances, and chose levels of mental and physical challenge that match their perceived capabilities. Person-situation transactions underscore the fact that personality functioning is not reactive but proactive. Individuals do not only react to the environments, but actively contribute to their transformation and creation. Individuals' distinctive ways of functioning reflect more than the unfolding of a genetic blueprint or the interactions which have taken place between the organism and the environment over the course of development. They also reflect individuals' active role in shaping their own personality.

Thus, one should look at adaptation as a dynamic, proactive process. People do not 'adapt' merely by altering themselves to fit environmental constraints and pressures. They select and transform environ-

ments in order to actualize their full potentials and maximize their own well being. Adaptation relies more on individuals' capacities to devise strategies and to implement tactics able to match successfully the requirements and affordances of multiple situations, than on fixed pattern of responses. The capacity to expand knowledge of oneself and of situations is no less important than the capacity to master such knowledge with the flexibility that is required by the variety and continuous change of person-situation transactions.

Over the course of life, people acquire competencies, knowledge about themselves and the social world, and standards for evaluating the worth of own actions. Self-reflective and self-directive processes enable individuals to meet environmental opportunities and constraints as well as to maintain personally valued courses of action in the relative absence of tangible rewards or social support. While people show a striking ability to adapt their behavior to physical, interpersonal, and social circumstances, and also to select and create the circumstances that best fit with their purposes and abilities, successful adjustment across the life span corresponds to the best allocation of personal and social resources within the set of temporally bound opportunities and constraints.

Thus selection, optimization, and compensation have been regarded as main strategies which attest the property of personality to capitalize upon experience in the achievement of higher levels of functioning and well-being. People must select life goals, activities, and pathways that are manageable; they must optimize the allocation of internal and external resources that are made available to them; they must develop strategies to compensate for lacks or losses of goal relevant means (Baltes 1997).

As people are causal agents who actively contribute to the course of their life in selecting and transforming the environment they encounters, adaptive behaviors are those behaviors that promote the conditions for the full expression of individual capacities and potentials. As individuals course of life is closely interdependent with the course of life of others, ultimately adaptive behaviors are those behaviors that serve for both the betterment of individual and collective welfare.

Future research should focus on psychological processes and social capacities that can strengthen people's capacity to adapt to a rapidly changing world. To this aim theories and findings are mostly needed to enable people to expand their knowledge and skills, to achieve greater emotional adjustment, and thus to fully realize their potentials.

Personality and Conceptions of the Self

A central aspect of personality involves the ways in which people perceive and think about themselves.

Unlike most nonhuman animals, human beings possess a capacity for self-reflexive thinking that allows them to think consciously about themselves in complex and abstract ways. People differ in the degree to which they self-reflect, the content and organization of their self-conceptions, the positivity of their self-evaluations, and the selves they desire and fear to become in the future. These differences in how people think about, characterize, and evaluate themselves underlie many of the characteristic patterns of thought, emotion, and behavior that comprise the human personality.

1. Self-attention

People differ in the amount of time that they spend attending to and thinking about themselves. Individual differences in self-attention have been studied most extensively in terms of the trait of self-consciousness. (As used in this context, self-consciousness refers only to the tendency to attend to oneself and does not involve the anxiety and awkwardness that everyday use of the term connotes.) People who are high in private self-consciousness—the tendency to think about inner, private aspects of oneself (such as one's motives, goals, attitudes, and feelings)—tend to behave more consistently with their attitudes, values, and goals than people who are low in private self-consciousness, presumably because self-attention increases people's adherence to their personal standards. Because their behavior is strongly influenced by their personal standards, people high in private self-consciousness display greater consistency in their behavior across different situations than those who are low in private self-consciousness (Carver and Scheier 1981).

Public self-consciousness—the tendency to think about the public, observable aspects of oneself (such as one's appearance, mannerisms, and image in other people's eyes)—is associated with the degree to which individuals try to control how they are perceived by other people (e.g., see *Impression Management, Psychology of*). Because they are more concerned with how they are perceived and evaluated by others, publicly self-conscious people conform more to group pressure, show greater concern for their physical appearance, and tend to be more socially anxious and embarrassed than people who are low in public self-consciousness (Carver and Scheier 1985).

Importantly, whether people are high in private or public self-consciousness has implications for how they perceive themselves. People high in private self-consciousness not only attend more to their private selves but also regard those private aspects of self as more important to who they are. In contrast, people high in public self-consciousness regard the public aspects of self as more salient and important.

2. Self-concept

The self-concept involves people's beliefs about their personal characteristics, not only beliefs about their traits, abilities, and physical attributes but also about their values, roles, and personal goals. People differ both in the content of their self-concepts (e.g., who and what they think they are) and in how the various elements of their self-concepts are organized. Again, these differences contribute to variations in personality.

Self-concepts develop through the individual's direct experience, as well as from the reflected appraisals of other people (e.g., see *Self-development in Childhood; Identity in Childhood and Adolescence*). Once formed, people's self-concepts exert a strong influence on their behavior. Perceiving oneself as a particular kind of person prescribes and proscribes certain actions. Seeing oneself as polite, for example, has implications for the behaviors that a person will and will not perform. As a result, people generally behave in ways that are consistent with the kind of person they think they are.

In addition, people's self-concepts provide them with information about the likely consequences of certain behaviors. Believing themselves to possess particular attributes leads people to expect certain outcomes to result from their actions. For example, a person whose self-concept included the trait 'intelligent' would have different expectations about performance in an academic setting than a person whose self-concept included the trait 'stupid.' Thus, the self-concept has implications for a person's sense of self-efficacy (e.g., see *Personality Development in Childhood*). Believing that one possesses particular attributes and abilities affects people's expectations regarding whether they ought to be capable of particular tasks, thereby influencing their motivation to engage in certain behaviors.

Research has supported James's (1890) notion that the self-concept is composed of multiple components. People's self-identities are composed both of personal aspects that characterize them without respect to other people (e.g., personal abilities, values, and goals) as well as social aspects that identify them with respect to their interpersonal roles and relationships (e.g., particular family relationships, friendships, and group memberships). People differ in the importance that they place on the personal versus social aspects of their self-identities (Cheek 1989), and these differences predict their behavioral choices and reactions to events. For example, people who place greater importance on the personal aspects of their identity seek jobs that allow them to fulfill personal goals (e.g., self-fulfillment, personal growth, expression of their values), whereas people who place greater emphasis on the social aspects of their identities seek jobs that provide desired social outcomes (e.g., recognition, an active social life, interpersonal relationships). People

with different prevailing aspects of identity also prefer different kinds of recreational activities—solitary activities that promote self-improvement for people who emphasize personal identity, and group activities that promote interpersonal relationships for people who emphasize social identity.

People generally try to maintain consistency among the various aspects of their self-concepts, as well as between their self-concepts and reality. People tend to be troubled by contradictions between two aspects of their self-concepts and when objective information discredits their self-perceptions, possibly because such inconsistencies undermine people's certainty in their beliefs about themselves and their worlds (e.g., see *Cognitive Dissonance*). In fact, receiving information that is inconsistent with one's self-concept may be distressing even if it otherwise reflects positively on the person. As a result, people are generally motivated to behave in ways that are consistent with their self-concepts and prefer interacting with those who see them as they see themselves. Thus, people's self-concepts tend to steer their behavior in directions that help to maintain and verify their existing self-views (Swann et al. 1987).

Beyond the fact that people hold different ideas of who they are and what they are like, people's self-concepts also differ in their clarity, complexity, and differentiation. First, people differ in the clarity and certainty of their self-concepts. People whose views of themselves are clear, confident, and certain tend to score higher in self-esteem and positive affect, and lower in depression and anxiety, than people who have unclear, unstable views of themselves (Campbell et al. 1996). People whose self-concepts are unclear or uncertain are also more easily persuaded than those with clearer and more certain self-concepts, and uncertain self-concepts are more likely to change due to experience or social feedback.

Second, people differ in self-complexity—the number of discrete ways in which they characterize themselves and in the interrelatedness of the various aspects of their self-concepts. Although initial research suggested that people with greater self-complexity are less strongly affected by negative life experiences (Linville 1987), refinements of the construct show that self-complexity bears a more complex relationship with emotional and behavioral outcomes than was first assumed (Gramzow et al. 2000, Woolfolk et al. 1995).

Third, people differ in self-concept differentiation—the degree to which they see themselves as having different personality characteristics when they are in different social roles (Donahue et al. 1993). People low in self-concept differentiation tend to see themselves as relatively constant across various social roles, whereas highly differentiated people see themselves quite differently in different roles. Although differentiation might seem to be beneficial because it promotes greater behavioral flexibility, research suggests that high

differentiation is generally undesirable, reflecting lack of an integrated core sense of self. Compared to people low in self-concept differentiation, highly differentiated people tend to be more depressed and anxious, lower in self-esteem, less agreeable, less satisfied with how they perform in their roles, and lower in self-control.

3. Self-evaluations

People not only see themselves as being a certain kind of person with particular sorts of attributes, but they also evaluate themselves in positive and negative ways, and experience corresponding positive and negative feelings when they think about who and what they are (e.g., see *Self-esteem in Adulthood; Self-evaluative Process, Psychology of*). Whereas self-concept refers to the *content* of people's beliefs about themselves, self-esteem refers to people's *evaluations* of those beliefs. Although people's evaluative feelings about themselves change across contexts and over time (i.e., state self-esteem), most research has focused on stable patterns of self-evaluation across situations (i.e., trait self-esteem). Researchers often refer to people having 'low' versus 'high' trait self-esteem, but, in reality, most people's trait self-esteem falls in the neutral to positive range, and relatively few individuals evaluate themselves negatively at a global level (Baumeister et al. 1989).

Trait self-esteem has proven to be an important psychological variable that predicts a great variety of emotions and behaviors. Self-esteem is generally correlated, albeit weakly, with indices of positive mental health such as low anxiety, neuroticism, and depression, and with a high sense of personal control and self-efficacy. However, self-esteem is also associated with maladaptive behaviors such as nonproductive persistence, risk-taking (particularly when the person's ego is threatened), and a tendency to make unrealistically self-serving attributions. Controversy exists regarding why self-esteem is related to behavior, thought, and emotion as it is. Various theories suggest that self-esteem is a marker of social dominance (dominance theory), a gauge of social acceptance (sociometer theory), a buffer against existential anxiety (terror management theory), and a reflection of personal autonomy (self-determination theory) (Hoyle et al. 1999).

People differ in the degree to which their positive and negative self-evaluations are confined to particular aspects of their self-concepts vs. spread across many aspects of the self. For people with highly compartmentalized self-concepts, positive and negative information about the self is confined to different aspects of the self; for people with self-concepts low in compartmentalization, positive and negative information is mixed across many aspects of self. Thus, two people may have an equal number of aspects of self

that they evaluate positively versus negatively yet differ in the degree to which these aspects are compartmentalized. Compartmentalization is associated with positive emotions and high self-esteem for people whose positive attributes are more important to them than their negative attributes. However, compartmentalization is associated with negative affect and low self-esteem for people whose negative attributes are more important (Showers 1992).

People differ also in the stability of their self-esteem. For some people, feelings of self-esteem change very little as they move from one situation to another, whereas the self-esteem of other people is quite labile, even over short spans of time. Thus, two individuals with the same general level of self-esteem may differ markedly in the degree to which their self-feelings vacillate. People with unstable self-esteem appear to possess fragile and vulnerable feelings of self-worth that are easily influenced by their experiences. They also tend to be more prone to anger and aggression when their self-esteem is threatened (Kernis and Waschull 1995).

4. *Desired and Undesired Selves*

People differ not only in how they perceive themselves at the present time but also in how they wish to be in the future. The human capacity for self-reflection allows people to imagine themselves in the future and to adjust their present behavior in ways that move them toward desired selves and away from undesired selves. These mental representations of desired and undesired future selves serve as incentives that motivate action, and as guides that channel behavior in particular directions (Markus and Nurius 1986). Interestingly, the future selves that people fear appear to exert greater power over their behavior than the selves that they desire (Ogilvie 1987).

A great deal of human emotion is a reaction to the fortunes of people's desired and undesired selves (Leary in press). People compare themselves and their outcomes in life to their desired and undesired selves, and experience various emotions depending on whether they are moving toward or away from their desired selves. Events that have positive implications for future desired selves evoke positive reactions, whereas events that have negative implications for desired selves (or, worse, indicate movement toward undesired future selves) cause emotional upset.

Self-discrepancy theory proposes that people's emotional reactions are strongly influenced by two particular sets of concepts about the desired self (Higgins 1987). According to the theory, people compare themselves to both an ideal self (how they would like to be) and an ought self (how they think they should be). A discrepancy between one's actual self and ideal self leads to dejection-related emotions such as sadness and disappointment, whereas a discrepancy between

actual and ought selves leads to agitated emotions such as anxiety and guilt. Research has generally supported the notion that self-discrepancies produce emotion, although not always precisely in the manner predicted by self-discrepancy theory.

5. *Future Directions*

Theorists have long recognized that people's real, desired, and feared self-conceptions underlie aspects of their personalities, and a great deal of research has investigated various relationships between the self and personality. However, the field lacks an overriding conceptual framework for understanding how different aspects of the self interrelate and how these aspects relate to personality structures and processes. An impending task for theorists and researchers is to integrate what is known about self-relevant aspects of personality within a single theory.

Personality and Crime

Psychology assumes that behavior arises from the interaction between the individual and the environment. Studies show that behavior is remarkably consistent over time; or, to be more precise, the relative ordering of individuals is remarkably consistent over time (Roberts and Del Vecchio 2000). It is assumed that behavioral consistency depends primarily on the persistence of underlying tendencies to behave in particular ways in particular situations. These tendencies are termed personality traits, such as impulsiveness, excitement seeking, assertiveness, modesty, and dutifulness. Larger personality dimensions such as extraversion refer to clusters of personality traits.

Many constructs assumed to underlie behavior are not included under the heading of personality. This is true, for example, of intelligence and moral reasoning abilities, and of cognitive processes (thinking, reasoning, and decision making). However, the boundaries between personality and all these constructs are not well defined. This review will focus on the topics conventionally included under the heading of personality, and there is not space here to discuss underlying biological processes in any detail.

The main types of offending studied are: burglary, theft, violence, vandalism, fraud, and drug abuse. Since crimes are a subset of antisocial acts, any potential to commit crimes is probably part of a broader potential

to commit antisocial acts, but the focus here is on crimes. The focus is also on normal personality, and as far as possible, discussions of related psychiatric conditions such as antisocial personality disorder, psychopathy, and attention deficit–hyperactivity disorder will be avoided. However, the boundary between normal and pathological behavior is not always clear, depending on judgments about how far normal functioning is impaired.

In studying the relationship between personality and crime, it is important to avoid tautological statements and tautological results. Any construct that is presumed to cause crime must measure something different from crime. Thus, it is useful to investigate how far low empathy causes crime but less useful to investigate how far aggressiveness causes violent crime or how far an antisocial personality causes crime. Early research using the psychopathic deviate scale of the Minnesota Multiphasic Personality Inventory and the socialization scale of the California Psychological Inventory was essentially tautological in showing that antisocial behavior was related to crime.

A bewildering number of personality traits and dimensions have been postulated, measured, and related to offending. In some cases, different terms are probably used to describe the same underlying construct. Only the most important topics can be reviewed here: temperament, impulsiveness, empathy, the Eysenck theory, and the ‘Big Five’ personality dimensions.

1. Temperament

Temperament is basically the childhood equivalent of personality, although there is more emphasis in the temperament literature on constitutional predisposition and genetic and biological factors. The modern study of child temperament began with the New York Longitudinal Study of Chess and Thomas (1984). Children in their first 5 years of life were rated on temperamental dimensions by their parents, and these dimensions were combined into three broad categories of easy, difficult and ‘slow to warm up’ temperament. Having a difficult temperament at age 3–4 years (frequent irritability, low amenability and adaptability, irregular habits) predicted poor adult psychiatric adjustment at age 17–24.

Remarkably, Bates (1989) found that mothers’ ratings of difficult temperament as early as age 6 months (defined primarily as frequent, intense expressions of negative emotions), predicted mothers’ ratings of child conduct problems between the ages of 3 and 6 years. Similar results were obtained in the Australian Temperament Project, which found that children who were rated as irritable, not amenable, or showing behavior problems at age 4–8 months tended to be rated as aggressive at age 7–8 years (Sanson et al.

1993). However, when information at each age comes from the same source, it is possible that the continuity lies in the rater, rather than the child. Fortunately, other studies (e.g., Guerin et al. 1997) show that difficult temperament in infancy, rated by mothers, also predicts antisocial behavior in childhood rated by teachers.

Because it was not very clear exactly what a 'difficult' temperament meant in practice, other researchers have investigated more specific dimensions of temperament. For example, Kagan (1988) and his colleagues in Boston classified children as inhibited (shy or fearful) or uninhibited at age 21 months on the basis of their observed reactions to a strange situation, and found that they remained significantly stable on this classification up to age 7 years. Furthermore, the uninhibited children at age 21 months significantly tended to be identified as aggressive at age 13 years, according to self and parent reports (Schwartz et al. 1996).

The most important results on the link between childhood temperament and later offending have been obtained in the Dunedin longitudinal study in New Zealand, which has followed up over 1000 children from age 3 years and into their 20s (Caspi 2000). Temperament at age 3 years was rated by observing the child's behavior during a testing session involving cognitive and motor tasks. The most important dimension of temperament was being undercontrolled (restless, impulsive, with poor attention), which predicted aggression, self-reported delinquency, and convictions at age 18–21 years.

2. *Impulsiveness*

The most important study of childhood temperament in relation to offending essentially identified impulsiveness as the key dimension, and it is generally true that impulsiveness is the most crucial personality dimension that predicts offending. Unfortunately, there are a bewildering number of constructs referring to a poor ability to control behavior. These include impulsiveness, hyperactivity, restlessness, clumsiness, not considering consequences before acting, a poor ability to plan ahead, short time horizons, low self-control, sensation-seeking, risk-taking, and a poor ability to delay gratification. Virtually all these constructs, measured in different ways, are consistently related to measures of offending (Blackburn 1993, pp. 191–196).

In a longitudinal study of over 400 London males from age 8 years to age 40 years, boys nominated by teachers as lacking in concentration or restless; those nominated by parents, peers, or teachers as the most daring or risk-taking; and those who were the most impulsive on psychomotor tests at age 8–10 years, all tended to become offenders later in life. Later self-report measures of impulsiveness were also related to

offending. Daring, poor concentration, and restlessness all predicted both official convictions, and self-reported delinquency, and daring was consistently one of the best independent predictors (Farrington 1992).

The most extensive research on different measures of impulsiveness was carried out in another longitudinal study of males (the Pittsburgh Youth Study) by White et al. (1994). The measures that were most strongly related to self-reported delinquency at ages 10 and 13 were teacher-rated impulsiveness (e.g., 'acts without thinking'); self-reported impulsivity; self-reported under-control (e.g., 'unable to delay gratification'); motor restlessness (from videotaped observations), and psychomotor impulsivity. Generally, the verbal behavior rating tests produced stronger relationships with offending than the psychomotor performance tests, suggesting that cognitive impulsiveness (based on thinking processes) was more relevant than behavioral impulsiveness (based on test performance).

There have been many theories put forward to explain the link between impulsiveness and offending. One of the most popular suggests that impulsiveness reflects deficits in the executive functions of the brain, located in the frontal lobes (Moffitt 1990). Persons with these neuropsychological deficits will tend to commit offenses because they have poor control over their behavior, a poor ability to consider the possible consequences of their acts, and a tendency to focus on immediate gratification. There may also be an indirect link between neuropsychological deficits and offending, which is mediated by hyperactivity and inattention in school, and the resulting school failure. In discussing links between executive functions and offending, impulsiveness may be difficult to disentangle from intelligence, although Lynam and Moffitt (1995) argued that they were different constructs. Various biological theories of impulsiveness have also been proposed, focussing on either behavioral activation or behavioral inhibition (e.g., Newman and Wallace 1993).

3. *Empathy*

There is a widespread belief that low empathy is an important personality trait that is related to offending, on the assumption that people who can appreciate and/or experience a victim's feelings are less likely to victimize someone. This belief also underlies cognitive-behavioral-skills training programs that aim to increase empathy. However, its empirical basis is not very impressive. There are inconsistent results in this field, and measures of empathy are not well validated or widely accepted. There appears to be no systematic comparison of different empathy measures analogous to the research of White et al. (1994) with impulsiveness, and no longitudinal study relating early measures of empathy to later offending.

A distinction has often been made between cognitive empathy (understanding or appreciating other people's feelings) and emotional empathy (actually experiencing other people's feelings). Eisenberg et al. (1998) further distinguished between sympathy (feeling concern for another) and experiencing personal distress. Empathy can be measured in many different ways, including self-completed questionnaires, peer ratings and systematic observation. Unfortunately, results vary according to the method used (Miller and Eisenberg 1988).

The best studies of the 1990s that have related empathy to offending in relatively large samples are by Mak (1991), Kaukiainen et al. (1999) and especially Luengo et al. (1994). In Australia, Mak (1991) found that delinquent females had lower emotional empathy than nondelinquent females, but that there were no significant differences for males. In Finland, Kaukiainen et al. (1999) reported that empathy (cognitive and emotional combined) was negatively correlated with aggression (both measured by peer ratings). In Spain, Luengo et al. (1994) carried out the first project that related cognitive and emotional empathy separately to (self-reported) offending, and found that both were negatively correlated.

Some results obtained in research on psychopathy are relevant. The Psychopathy Checklist includes two correlated factors, the first measuring personality and the second measuring an antisocial life-style (Harpur et al. 1988). The first factor measures a cold, callous personality, lacking empathy, affect, guilt and remorse, and engaging in habitual lying and manipulation. This constellation of personality traits is correlated with conduct problems and delinquency. Further research on it is warranted, especially in prospective longitudinal studies.

4. The Eysenck Theory

Before 1990, the best-known research on personality and crime was probably that inspired by Eysenck's theory and personality questionnaires (Eysenck 1996). He viewed offending as natural and even rational, on the assumption that human beings were hedonistic, sought pleasure, and avoided pain. He assumed that delinquent acts, such as theft, violence, and vandalism were essentially pleasurable or beneficial to the offender. In order to explain why everyone was not a criminal, Eysenck suggested that the hedonistic tendency to commit crimes was opposed by the conscience, which was viewed as a fear response built up from childhood in a conditioning process.

On the Eysenck theory, the people who commit offenses are those who have not built up strong consciences, mainly because they have inherently poor conditionability. Poor conditionability is linked to Eysenck's three dimensions of personality, Extraversion (E), Neuroticism (N), and Psychoticism (P).

People who are high on E build up conditioned responses less well, because they have low levels of cortical arousal. People who are high on N also condition less well, because their high resting level of anxiety interferes with their conditioning. Also, since N acts as a drive, reinforcing existing behavioral tendencies, neurotic extraverts should be particularly criminal. Eysenck also predicted that people who are high on P would tend to be offenders, because the traits included in his definition of psychoticism (emotional coldness, low empathy, high hostility, and inhumanity) were typical of criminals. However, the meaning of the P scale is unclear, and it might perhaps be more accurately labeled as psychopathy. Zuckerman (1989) suggested that it should be termed 'impulsive unsocialized sensation-seeking.'

A review of studies relating Eysenck's personality dimensions to official and self-reported offending concluded that high N (but not E) was related to official offending, while high E (but not N) was related to self-reported offending (Farrington et al. 1982). High P was related to both, but this could have been a tautological result, since many of the items on the P scale are connected with antisocial behavior, or were selected in light of their ability to discriminate between prisoners and nonprisoners. In the prospective longitudinal study of London boys, those high on both E and N tended to be juvenile self-reported offenders, adult official offenders and adult self-reported offenders, but not juvenile official offenders. These relationships held independently of other criminogenic risk factors, such as low family income, low intelligence, and poor parental child-rearing behavior. However, when individual items of the personality questionnaire were studied, it was clear that the significant relationships were caused by the items measuring impulsiveness (e.g., doing things quickly without stopping to think). Hence, it seems likely that research inspired by the Eysenck theory essentially confirms the link between impulsiveness and offending.

5. The 'Big Five'

Since 1990, the most widely accepted personality system has been the 'Big Five' or five-factor model (McCrae and Costa 1997). This suggests that there are five key dimensions of personality: Neuroticism (N), Extraversion (E), Openness (O), Agreeableness (A) and Conscientiousness (C). Openness means originality and openness to new ideas, Agreeableness includes nurturance and altruism, and Conscientiousness includes planning and the will to achieve. Openness and Conscientiousness seem related to intelligence, or at least to social or emotional intelligence. These dimensions are measured using a personality inventory called the NEO-PI. Controversially, McCrae et al. (2000) argued that these personality dimensions are biologically based tendencies that follow intrinsic

developmental pathways independently of environmental influences.

Because of its newness, the 'Big Five' personality model has rarely been related to offending. In Canada, Hart and Hare (1994) found that psychopathy was most strongly (negatively) correlated with Agreeableness and Conscientiousness. Similarly, in an Australian study Heaven (1996) showed that Agreeableness and Conscientiousness were most strongly (negatively) correlated with self-reported delinquency. Much the same results were obtained in the Pittsburgh Youth Study when the five dimensions were measured using mothers' ratings (John et al. 1994). It seems likely, therefore, that this pattern of results is replicable.

6. Future Directions

More research is needed on the theoretical linkages between personality constructs and offending and on their biological bases. Prospective longitudinal studies are especially needed in which personality traits are measured early in life and related to later offending, to investigate the relative importance of biological, individual, family, peer, and school influences on personality and crime. Different studies should be compared to investigate how far results are replicable across genders, races, and cultures (Caspi et al. 1994).

A key issue that has rarely been addressed is the relationship between personality dimensions and different types of offenders. It might be expected, for example, that violent offenders would be more impulsive than non-violent offenders. It would be useful to use personality traits to define types of people and hence move from a variable-based to a person-based approach (Krueger et al. 1994).

The main policy implication of research on personality and crime is the use of cognitive-behavioral skills training techniques to try to counteract high impulsivity and low empathy. Research on childhood temperament suggests that potential offenders can be identified early in life and that efforts should be made to change children with uninhibited and uncontrolled temperaments. Research on personality and crime should also be useful in matching types of people to types of interventions. It seems likely that different personality types would interact differently with different criminological risk factors, and hence that interventions should be tailored to personalities. This is the new frontier.

D. P. Farrington and D. Jolliffe

Personality and Health

1. Associations between Personality and Health: Background

It is common folk wisdom that people who worry too much are likely to develop headaches, that nervous people are prone to ulcers, that excitable people are likely to develop skin rashes, and that overly sensitive people may be prone to nausea or fainting. Popular wisdom also has it that workers who strive compulsively for long hours at frustrating job tasks are more likely to have heart attacks, and that people who

bottle up all their feelings inside them have an increased risk of cancer. Yet the scientific evidence suggests a different and more complex picture. Further, although there are indeed associations between personality and health, the causal links are not always what they first appear to be. This is important because the causal linkages tell us which interventions are helpful and which are worthless or even possibly harmful.

A significant ethical danger in studying the relations of personality and health is that individuals may be unfairly blamed for their health problems. Health and illness are complex states, usually influenced by a wide variety of biological, environmental, and psychosocial factors. Personality—the traits, motives, emotions, and behavioral patterns unique to each individual—is sometimes associated with illness, but it would be a grave oversimplification to think that the individual has direct responsibility for his or her health. On the other hand, individual behavior patterns sometimes do affect health-relevant processes, and so the person, the family, the environment, and the culture can sometimes promote the likelihood of better health.

1.1 Roots in Ancient Greece

The idea that personality and health might be related dates back thousands of years and clearly appears in the writings of Hippocrates, Galen, and their followers. The ancient Greeks, keen observers of the human condition, saw four elements, the so-called bodily humors, as key to both individuality and health. People with a healthy supply of blood might turn out to be sanguine and ruddy. Black bile (or melancholy) might lead to depression and degenerative diseases or cancer. Yellow bile (or choler) could produce a bitter, angry personality and associated diseases, and phlegm is characteristic of a phlegmatic, cold apathy. It is interesting that this scheme of four emotional aspects of personality and health was sufficiently perceptive (or ambiguous) to influence the practice of medicine for 2,000 years. Of course, notions of bodily humors have been discarded. Yet the idea that individuals can be categorized as sanguine, depressed, hostile, and repressed continues to stay with us. Modern personality and health psychology takes these chronic psycho-emotional states and combines them with a more sophisticated understanding of traits to study the associations among personality and health.

1.2 Type A Behavior

Much of the current research interest in personality and health began with theory and research on the Type A Behavior Pattern (Houston and Snyder 1988). Early in the twentieth century, a number of prominent physicians including William Osler began noting that

certain men seemed especially prone to angina and coronary heart disease. The at-risk characteristics supposedly included being ambitious, hard-working, dominant, and aggressive. In the 1930s and 1940s, the influence of psychoanalysis on psychosomatic medicine led to numerous speculations about the role of expression and repression of hidden conflicts and anger on the development of heart disease. But it was not until the mid-century writings on Type A behavior that empirical research on this topic began in earnest.

The term 'Type A' was chosen by its inventors Meyer Friedman and Ray Rosenman (e.g., Rosenman et al. 1975) because it was a nonconnotative, 'objective' designation for a so-called coronary-prone medical syndrome. Type A people were seen as struggling rapidly to accomplish many things in a short period of time, always with a deadline to meet. They were viewed as very competitive, active, and quite hostile or aggressive. Although any person can act this way from time to time, Type A people were seen as constantly driven. Individuals who did not fit this profile were labeled, by default, as Type B. That is, there was thus no independent definition of what a healthy personality style might be.

Although many hundreds of studies have been conducted on Type A behavior, the results have often been mixed and confusing. Although the initial aim was to simplify the concept by choosing a neutral term ('Type A') and avoiding related psychological concepts and theories, the characteristics of individuals cannot be adequately explained in such a sterile manner. That is, psychologists soon turned to trying to understand the trait correlates of Type A behavior, the components of Type A behavior, the basis of Type A behavior, the consequences of Type A behavior, and the health aspects of Type A behavior, even beyond coronary disease (Friedman 1992, Houston and Snyder 1988, Miller et al. 1996).

It is now clear that the fast speed and the job-involvement aspects are not important predictors of coronary disease. However, excessive competitiveness and constant hostility seem, for some people in some circumstances, to increase the likelihood of coronary heart disease. It is not yet clear the extent to which these characteristics also raise the risk of all-cause mortality, since there has been insufficient attention to construct validity.

The idea of Type A behavior proved to be an important heuristic one, leading to much empirical research since the 1970s about whether, when, why, and how personality plays a role in health. There are, however, a variety of possible mediating mechanisms.

2. Ways that Personality is Related to Health: Causal Links

There are many different reasons why personality is associated with health. Understanding the causal

pathways is very important, because an interest in this subject usually derives from a desire to improve or promote health. However, it turns out that personality can affect health, that health can affect personality, or that the association between them can be the result of several sorts of artifacts.

2.1 Symptom Reporting and Medical Usage

It is well documented that personality is related to symptom reporting, symptom sensation, and entering the medical care system. Certain people, especially people who are neurotic, with anxiety and stress, are more likely to report symptoms including headache, gastrointestinal distress, and other assorted aches and pains. In other words, if questioned closely, other, non-neurotic people would be experiencing the same symptoms but would not be as likely to talk about them or to report them to their physicians.

It is also the case that people with anxiety and stress are more likely to feel pain and other symptoms. That is, they have a lower threshold for experiencing pain and a lower tolerance for pain. They also may be especially vigilant about bodily sensations (Friedman 1991/2000, Pennebaker 1982).

People with certain psychological traits are also more likely to enter the health care system. These people are generally characterized by such traits as anxiety, depression, dependency, hostility, and moodiness. Women are also generally more likely to seek health care than men. In the extreme, there are people with factitious disorders who seek health care for the rewards that they receive there, including attention, drugs, and shelter (Costa and McCrae 1987, Friedman 1990).

In all of these cases, there are associations between personality and ill health, but the association results from a greater tendency to report and perceive symptoms and seek treatment rather than from a greater incidence of organic disease. In other words, in many cases, certain people are more likely to report being 'ill,' but they do not differ much from other people in their incidence of clear organic diseases like heart disease or cancer.

2.2 Disease-caused Personality Changes

Many associations between personality and health are the result of disease processes that affect health. Certainly any disease with a significant impact on the brain, including Alzheimer's, Parkinson's, strokes, syphilis, AIDS, and brain tumors can produce associations between personality and health. Since the changes in personality often become apparent long before the changes in organic brain function are examined and diagnosed, it may appear that the personality is predicting or even causing the disease

when the reality is that the disease is changing the personality (Woodward 1998).

In many people, the processes are likely even more subtle and complex. Various illnesses affect the blood supply to the brain, the neurotransmitters in the brain, and communication from other parts of the body to the brain (Woodward 1998). This may result in various associations between personality and health, especially involving depression or other mood changes. For example, low levels of thyroid hormones or lessened oxygen in the blood can cause depression. Importantly, many if not most prescription and non-prescription drugs, being used to treat illness, can affect the brain and thus affect mood and personality, sometimes dramatically, sometimes subtly.

2.3 Temperamental Underlying Third Variables

Some of the associations between personality and health result from a constitutional predisposition underlying certain aspects of personality and certain threats to health. For example, some people's cardiovascular systems are hyper-reactive, meaning that their blood pressure and heart rate may show marked increases when the individual is under stress. As part of this biology, such people are more likely to be introverted and neurotic (aspects of personality) and are also more likely to suffer diseases such as hypertension. In such cases of an underlying third variable, it is not necessarily the case that efforts to change personality (such as helping an introvert become more sociable) will have any effect on health risk if the underlying physiology is not altered (Eysenck 1991, Friedman 1990, Zuckerman 1991).

Similarly, a hostile temperament, which may result from a combination of genetics, early hormone exposures, and early experiences, could lead to an association between a choleric personality and health risks. Hans Eysenck has argued that such psychobiological systems produce many associations between individual characteristics and disease, but also that the psychobiological characteristics are modifiable, thus producing changes in both personality and disease risk.

2.4 Personality-caused Illness

Probably the most interesting link between personality and health arises when personality has a fairly direct, causal influence on health. For example, chronic worrying and distress somehow may increase the likelihood of headaches. Since we cannot randomly assign people to personality and do conclusive experiments, inferences about how personality affects health must necessarily be inexact. It is important to employ a wide variety of studies ranging from epidemiological studies of psychological patterns and health down to

biological studies of the physiological correlates of personality. The findings must then be pieced together.

3. Explanations of Personality-caused Illness

In those cases in which personality affects health, it is useful to distinguish among several primary causal pathways. However, given that these influences occur across time, it is often the case that these mechanisms do not function independently; rather they feed back on and interact with each other (Antonovsky 1979, Bolger and Zuckerman 1995, Friedman 1991/2000).

3.1 Poor Coping

Personality is related to coping, the ways in which an individual contends with stress. New thoughts and behaviors are constantly necessary to adapt to new challenges. With successful coping, the individual interprets and understands the challenge, draws on helpers to address it, and takes appropriate actions. Depending on the challenge, individuals who are depressed, introverted, repressed, unconscientious, vain, or conflicted may be less successful in bringing to bear necessary psychological, social, and behavioral resources (Aspinwall and Taylor 1997, Friedman 1991/2000).

A common issue involves relying on unproductive psycho-emotional ways of coping when a behavioral action could be used to solve the problem or source of stress. For example, a student might go party rather than study to deal with the challenge of an upcoming major exam. On the other hand, an individual might attempt to change the unchangeable. For example, after injury or loss, a person may need to find psychological ways of dealing with his or her new situation in order to cope effectively. Poor coping can lead either to unhealthy behaviors or unhealthy physiological reactions, or both (Maddi and Kobasa 1984, Pennebaker 1995).

3.2 Unhealthy Behaviors

It is well documented that certain personalities in certain situations are more likely to engage in unhealthy behaviors such as smoking, drinking, drug abuse, fast driving, fighting, and so on. Certain people are also less likely to engage in prophylactic measures such as using sunscreen, wearing seat belts, using condoms, brushing teeth, regularly washing hands, and so on. Some individuals are more or less likely to visit physicians, keep follow-up appointments, follow medical regimens, or have screening tests. Since these associations usually depend on at least several factors about the individual, the situation, and the unhealthy

activity, it is not usually possible to offer simple, broad generalizations.

3.3 Stress and Physiological Reactivity

Psychophysiological mechanisms often come to mind when one first considers links between personality and health. This is the idea that personality and stress directly impact internal physiological processes, thus causing disease. A more general view here is that the disruption upsets bodily homeostasis, thus allowing disease to take hold.

Much of this work dates back to Walter Cannon's writings on the 'fight-or-flight' response in which catecholamines are released and affect organs and systems throughout the body. Catecholamines (such as epinephrine) can affect processes from heart rate and blood pressure to the metabolism of fats. More recently, it has been established that the immune system is likewise affected by stress hormones. It is well documented that certain people are more likely than others to react to challenge with significant psychophysiological stress reactions (Denollet 1998, Friedman 1992, Kiecolt-Glaser et al. 1998, Zuckerman 1991).

3.4 Tropisms: Seeking Unhealthy Situations

One of the least understood but most intriguing sources of the link between personality and disease involves unhealthy situations. Some individuals gravitate towards healthier and health-promoting psychosocial environments, while other individuals find themselves pulled towards unhealthy environments. In these instances, it is not the case that personality leads directly to unhealthy behaviors or to unhealthy psychophysiological reactions. Rather, the personality facilitates entering the unhealthy situation.

Some of this motivation is derived from genetics, temperament, and early experiences. Other motivation arises from family experiences and consistent peer pressure. People who are impulsive, hostile, psychologically unstable, and have related difficulties in self-regulation are more likely to find themselves in environments that promote smoking, alcoholism, drug abuse, interpersonal violence, promiscuity, and risk-taking hobbies. Furthermore, neuroticism tends to predict to negative life events; in other words, neurotic people are more likely to experience objectively more stressful events (Taylor et al. 1997). Others, who are well socialized, conscientious, and agreeable, are more likely to wind up well educated and surrounded by mature adults. Note that someone who was genetically predisposed to alcoholism or other addiction is very unlikely to develop the health-impairing problem if raised in and exposed to very healthy psychosocial environments.

4. Disease-prone Traits

Although studies rarely assess a variety of personality traits, a variety of likely mediating mechanisms, and a variety of health outcomes, efforts to piece together the results of different types of research yield a sense of which characteristics are more or less likely to lead to good health.

4.1 Extraversion

Various theories suggest that extraversion and its components of dominance, sociability, and talkativeness should be related to good health, but the evidence is sparse. It is certainly the case that people who are well integrated into their communities, have friends, and have good relations with others are more likely to be healthier. Such social support is not, however, necessarily derived from being highly extroverted. Closer analysis reveals many people who are not especially extroverted but who have important, stable social relationships.

4.2 Optimism

Derived from popular notions of the importance of 'positive thinking,' a good deal of research has examined whether optimism is related to health. Optimism is the general expectation that good things will happen. To the extent that optimists may try harder when challenged, take better care of themselves, and cope better with the adversity of illness, optimism may sometimes be a characteristic of good health. For example, dispositional optimists tend to have a faster rate of recovery from coronary bypass surgery (Aspinwall and Taylor 1997, Scheier et al. 1989). Faster recovery with a positive outlook may also be a result of improved immune system functioning as stress is reduced (Kiecolt-Glaser et al. 1998).

However, there are also many reasons why optimism is not health protective and may be health damaging. The other side of the coin of optimism is 'optimistic bias' or unrealistic optimism (Weinstein 1984). This bias involves the faulty belief that negative events are less likely to happen to the optimist than to others. For example, one might agree that 'people' who smoke and who do not eat fruits and vegetables are more likely to get cancer, but not worry at all whether the relationship applies to oneself. Importantly, someone who is too optimistic may not take precautions or may not cooperate fully with medical treatment (Peterson et al. 1998, Tennen and Affleck 1987).

4.3 Neuroticism, Hostility, Depression

It is very well established that individuals who are more anxious, hostile, or depressed are more likely to

report being ill and seek medical care. Much research controversy has arisen over the extent to which and the circumstances under which these are causal mechanisms, with these personality traits causing disease. As noted, such individuals are more likely to feel, report, and treat symptoms. It is also often the case, however, that these symptoms result from true organic disease, promoted by psychological causes.

The best evidence concerns hostility, which was first investigated in an attempt to better understand coronary proneness. Chronic hostility (and chronic arousal of the sympathetic nervous system) raises the risk of disease and interferes with recovery (Miller et al. 1996).

There is also mounting evidence of the role of chronic depression in increasing the likelihood of development of various illnesses. Depression is associated with cortisol dysregulation, which is also linked to disruptions in lipid metabolism. It is not yet clear whether this is closely tied to hostility or is a different mechanism.

The aspect of neuroticism that is characterized by alienation, anxiety, and pessimism can produce various unhealthy effects. Such people can turn to substance abuse or overeating in an attempt to regulate their anxious states. They may develop insomnia. They may avoid interpersonal assistance and medical assistance. This may lead to a cycle of increasing anxiety, isolation, and health problems. On the other hand, someone whose neuroticism leads to a vigilance about avoiding threats, attending to symptoms, and cooperating with treatment may gain some health benefits.

Some researchers focus more generally on chronic negative affect, which includes both emotional distress like anxiety and depression as well as social interaction such as introversion, alienation, and the inability to express oneself to others. This distressed personality is sometimes referred to as 'Type D' (Denollet 1998).

4.4 Conscientiousness and Impulsivity

With significant attention to variables such as chronic hostility and Type A competition, it is perhaps not surprising that certain key aspects of a healthy personality have not been uncovered until recently. There is, however, rapidly growing evidence that conscientiousness and a lack of impulsivity is a key characteristic of healthy individuals. Conscientious people, who are prudent, planning, persistent, and dependable, tend to succeed in various life tasks, including staying healthy.

One major study of individuals who have been followed from childhood until their deaths in adulthood, conducted by Howard Friedman and his colleagues, has repeatedly found evidence that conscientiousness is the key personality predictor of longevity. Interestingly, the protective effect of con-

scientiousness does lessen the likelihood of death from accident and injury, but it is also protective against death from diseases such as cardiovascular disease and cancer. Conscientiousness does not seem to have its effects simply through one or two behavioral pathways, but rather it seems to affect a whole host of threats to health (Friedman et al. 1995). This finding of the importance of conscientiousness has been confirmed by subsequent studies by others which show that conscientiousness is associated with healthy behaviors, better self-care, better cooperation with medical treatment, and risk avoidance.

4.5 Repression, Lack of Verbalization, and Lack of Disclosure

It has long been recognized that among the many people who seem disease-prone, not all are hostile, impulsive, or neurotic. There are some who are too stoic, apathetic, and unemotional. These phlegmatic people, who look cool, calm, and sluggish, may be consciously or unconsciously suppressing or repressing inner conflict or feelings. This phenomenon is not well understood, but such people may appear tense or anxious upon close observation, although they assert friendliness and cooperation. Such people are often alienated or feel powerless.

A behavior pattern involving a repressive or denying coping style, lack of emotional expression, stress and anxiety, and helplessness/hopelessness is sometimes referred to as 'Type C.' A similar pattern in which individuals are unable to express emotion and seem at higher risk of disease progression is sometimes studied under the rubric of 'alexithymia.' There is speculation that such conditions promote the development or the progression of some cancers, but the relationship of this constellation of traits to other illnesses has not been much studied.

James Pennebaker has proposed that inhibition is a form of physiological work that increases the risk of illnesses. On the other hand, people who can talk about emotional experiences seem to set in motion processes to better health. Verbalizing may contribute to cognitive assimilation of stress and/or help people understand and organize their experiences. It may also often lead to increases in levels of social support.

5. Self-healing Personality

Although most theory and research has focused on disease-prone personalities, it is equally important to examine the characteristics that are associated with good health and longevity. These characteristics are not necessarily simply the absence of the disease-prone traits.

The 'Self-healing personality' refers to a healing emotional style involving a match between the in-

dividual and the environment, which maintains a physiological and psychosocial homeostasis, and through which good mental health promotes good physical health. The term was proposed by psychologist Howard S. Friedman in his 1991 book of the same name (Friedman 1991/2000). Self-healing, emotionally balanced people may be calm and conscientious but are responsive, energetic, curious, secure, and constructive. They are also people one likes to be around. People with self-healing personalities have better odds of a longer, healthier life.

Self-healing individuals often appear enthusiastic, and they may move in smooth, synchronized styles. Their relative lack of emotional conflict and anxiety may result in fewer speech disturbances, modulated voice tones, and an emotional consistency. Contrary to some common wisdom, a self-healing style does not involve a lack of challenge. In fact, self-healing individuals are often found in challenging, socially valued careers. They may enjoy stimulating travel because they are curious and enjoy exploration.

Interestingly, self-healing personalities are often similar to the mentally healthy orientations that have been described by humanistic psychologists (Antonovsky 1979, Csikszentmihalyi 1991, Maddi and Kobasa 1984). Humanistic psychologists such as Abraham Maslow thought that they were describing mental health when they wrote about self-actualized people who are concerned with issues of beauty, ethics, and justice. But it turns out that this spontaneous, positive, growth orientation is also associated with physical health. Indeed, it is a false dichotomy to divide physical and mental health in these ways. This positive process is sometimes also referred to by Mihaly Csikszentmihalyi as 'flow.'

5.1 Efficacy and Hardiness

Work by Salvador Maddi and Suzanne Ouellette Kobasa helped provide a framework for thinking about staying healthy in the face of challenge. They call these personality attributes hardiness. First, they suggest that a healthy personality maintains a sense of control. This is not necessarily a wild sense of optimism, but rather a sense that one can control one's own behaviors. Second, there is a commitment to something that is important and meaningful in their lives. This may also involve values and goals. Third, hardy people welcome challenge. For example, they may view change as an exciting challenge to their growth and development. Efficacy and hardiness generally involve a productive orientation, a sense of mastery, and a zest for life (Bandura 1997).

5.2 Salutogenesis

The medical sociologist Aron Antonovsky (1979) proposed an approach termed 'salutogenesis,' a theory

of how and why certain people stay healthy. What is interesting about this approach is that it does not postulate a sense of control as a primary or even necessary characteristic of a healthy personality. Rather, Antonovsky refers to a 'sense of coherence' which is central to successful coping with challenge. Coherence means that the world is understandable, manageable, and meaningful. In this scheme, someone who believes that nature or a divine force is in charge of the world could have a very healthy orientation, even though the individual does not have a personal sense of control. There is so far only scattered evidence to support this promising approach.

6. Conclusion

In sum, certain individuals are predisposed to be vulnerable to physiological, psychosocial, and interpersonal disturbances and stresses due to a combination of genetics, emotional temperament, and early experiences. When such individuals seek out or are placed in environments that bring out, create, or exacerbate these disturbances, chronic stress patterns may result. These may be accompanied by unhealthy behaviors such as substance abuse. When these individuals then encounter microbes, toxins, or excesses such as high-fat diets, the likelihood of illness increases significantly. On the other hand, other individuals have developed processes of self-healing, which build on themselves as healthier emotional styles, physiological reactions, behaviors, and social interactions become mutually reinforcing.

Overall, there is good evidence that individual characteristics are sometimes tied to health through the biological, psychological, and social aspects of personality, and there is some evidence that focused interventions can have short-term salutary effects on health. But relatively little is understood about the precise causal inter-relations of physiology, coping, social influence, and health behavior, and little is known about the extent to which a focus on personality alone can have substantial effects on various significant health outcomes. It will be important in the future to unravel how these key processes come together and affect each other, both across short time periods and across the lifespan.

Personality and Marriage

The success or failure of a marriage is likely to depend, at least in part, on the personality of the individual spouses, broadly defined as the set of enduring traits and characteristics that each spouse brings to the relationship. Three questions have motivated most research on the role of personality in marriage. First, what personality traits are most relevant to predicting marital outcomes? Second, does similarity or dissimilarity between partners’ personalities affect marital outcomes? Third, through what mechanisms does the personality of each spouse affect the relationship? This article reviews each of these areas of research in turn.

1. Which Personality Traits Affect Marital Outcomes?

The earliest efforts to predict marital outcomes were guided by the belief that ‘a large proportion of incompatible marriages are so because of a predisposition to unhappiness in one or both of the spouses’ (Terman 1938, p. 110). To explore the support for this belief, the first marital researchers conducted two kinds of studies: cross-sectional studies, in which lengthy personality inventories were administered to samples that included happily married and distressed couples, and longitudinal studies, in which personality inventories were administered to engaged couples whose marital quality was assessed several years later. Early marital researchers were more interested in determining whether spouses’ personalities accounted for marital outcomes than in identifying which aspects of personality were associated with marital outcomes. Thus, the results of these initial studies were frequently reported in terms of a global personality score rather than divided into specific personality traits. Nevertheless, when Burgess and Wallin (1953), in the first review of this literature, concluded that success and failure in marriage could be predicted by the person-

alities of each spouse, they noted that personality traits associated with neuroticism (e.g., irritability, moodiness, ill-temper) appeared to be especially predictive. Spouses who reported an enduring tendency to experience negative affect across a variety of contexts seemed to be at greater risk of developing marital distress.

As these results accumulated, the same researchers noticed that other enduring characteristics of the spouses (e.g., childhood family environment, sexual history, demographic variables), were also significant predictors of marital outcomes. Once statistical techniques for conducting multiple regression became widely available, a second wave of research examined the ability of personality traits to account for marital outcomes relative to these other sources of influence. Perhaps the most impressive of these studies is that of Kelly and Conley (1987), who followed a sample of 300 couples for over 40 years. At the initial phase of data collection, engaged partners provided self-reports of their early family environment, attitudes towards marriage, sexual history, and stressful life events. In addition, the researchers contacted five acquaintances of each partner and asked these individuals to rate the personality of the subject, a substantial improvement over the self-report inventories relied on by most prior (and subsequent) studies of personality. When all of these variables were examined at the same time, only the personality ratings emerged as significant predictors of marital stability. Specifically, compared to marriages that remained intact, couples whose marriages dissolved over the course of the study were characterized by higher levels of neuroticism in both spouses and higher levels of impulsivity in husbands.

In the late 1980s, the development of the five-factor model of personality briefly promised to expand the focus of marital research beyond the negative aspects of spouses' personalities. According to this model, the many traits that had been studied in prior research on personality could be adequately summarized by five relatively independent dimensions: neuroticism, impulsivity, extraversion, agreeableness, and conscientiousness. Emerging support for this model lead marital researchers to ask whether dimensions of the 'Big Five' besides neuroticism and impulsivity may also be associated with marital outcomes. Thus, for example, Kurdek (1993), in a five-year study of newlywed couples, examined the ability of each of the five personality dimensions to predict the quality and stability of marriages over time. This study did find that wives' conscientiousness was weakly but positively associated with the stability of the marriage over five years. However, echoing the results of previous research, far larger effects were obtained for the neuroticism of both spouses. Karney and Bradbury (1995), in a meta-analysis of longitudinal research on personality and marriage, reported that of all of the Big Five personality dimensions, only neuroticism had demonstrated consistent effects on marriage across

multiple studies. As the first marital researchers suggested, a spouse's 'predisposition to unhappiness' appears to predict decline and instability in marriage more reliably than other personality traits.

2. Similarity and Complementarity

As research on personality in marriage has developed, some have argued that the content of each spouse's personality may be less important to understanding marital outcomes than the degree of similarity between spouses' personalities. The assumption of this perspective is that spouses who share similar personalities should experience fewer opportunities for conflict and thus decreased risk of marital dissolution. Bentler and Newcomb (1978) offered some support for this view in a longitudinal study of newlywed couples. Although each spouse's level of extraversion had no independent association with their marital outcomes, the correlation between husbands' and wives' extraversion scores was significantly higher among couples who remained married than among couples who divorced.

Despite the intuitive appeal of this perspective, the accumulation of further support has been limited by a number of difficulties in assessing the effects of similarity in couples. First, the effects of similarity on a given trait are rarely independent of the effects of the trait itself. For example, Kurdek (1993) found that the difference between husbands' and wives' levels of neuroticism was greater in marriages that dissolved than in marriages that remained intact. This finding may support the role of personality similarity in marriage, but it may also result from the fact that differences between spouses are likely to be larger in couples where levels of neuroticism in either partner are higher overall. Estimating the unique effects of similarity between spouses requires that the effects of each spouse's personality be accounted for first. This is a control that has rarely been implemented.

A second difficulty with this kind of research is the fact that, as Kenny and Acitelli (1994) pointed out, 'A couple may appear to be very similar in their responses, yet they may be no more similar than a man and a woman who are totally unacquainted' (p. 419). Because there may be a typical way that most people tend to respond to personality inventories, the personalities of randomly matched people are likely to be similar to some degree. Estimating the unique degree of similarity in a given marriage requires that the 'typical cultural response' be controlled, but again this is a control that has rarely been implemented.

When similarity between spouses has been estimated accurately, support for beneficial effects of similar personalities has been sparse. For example, Russell and Wells (1991) reported that after controlling for the independent effects of each spouse's responses to a personality inventory, the association between marital satisfaction and the differences between spouses'

responses was rarely significant. Furthermore, the overall association between spouses' personalities tends to be weak (Buss 1984), even though spouses tend to be highly similar to each other on many other dimensions. In general, this research suggests that it may be spouses' similarity on those other dimensions, and in particular the degree to which spouses are similar in their values and attitudes, that may be more relevant to account for marital outcomes. With respect to personality, the nature of each spouse's personality appears to be more important than the degree of similarity between them.

In contrast to the similarity perspective, a competing view suggests that it is the degree of complementarity in spouses' personalities that is key to the successful marriage. For example, Winch (1958) argued that spouses select each other to resolve inadequacies in their own characters. Thus, extraverted people should be happiest with introverted partners and domineering people should be happiest with submissive partners. Although this is also an intuitively appealing idea, to date all attempts to obtain empirical support for the complementarity hypothesis have failed.

3. How Does Personality Affect Marital Outcomes?

Having established that personality traits, especially those associated with neuroticism, predict marital outcomes, the current focus of research on personality and marriage is to explain how this association comes about. Caspi et al. (1989), in their work on the effects of personality throughout the life course, proposed a broad framework that may be applied to understanding this issue. These researchers described two kinds of processes through which personality may affect development throughout the life course. 'Cumulative continuity' refers to all of the ways that individuals' personalities channel them towards certain environments and opportunities. 'Interactional continuity' refers to all of the ways that individuals' personalities affect their behavior towards and cognitions about other people. There is substantial evidence that both of these processes may account for the effects of spouses' personalities on their marriages.

3.1 Cumulative Continuity in Marriage

From early childhood, the personality of an individual affects not only the environments selected by the individual but also the opportunities available to the individual. Thus, for example, children who are prone to negative moods may choose career paths that are compatible with their temperament, but their choices may also be restricted by the behavioral consequences of their temperament (e.g., poorer educational at-

tainment, lower professional accomplishment). In this way, individuals' personalities may have cumulative consequences that greatly shape the context of their adult lives. The nature of their adult environments may in turn affect the quality of individuals' marital relationships. For example, women who experience chronic depression as adolescents tend to marry at a younger age compared to women who do not experience chronic depression (Gotlib et al. 1998). Age at marriage is associated with risks of divorce, such that people who marry at a younger age are at higher risk for divorce than people who marry later in life. Thus, the stable tendency to experience negative affect in childhood appears to be associated, at least for women, with a life course that is detrimental to marriage.

In a similar vein, the personality characteristics of each spouse may give rise to stressful events and circumstances that impact the relationship. For example, individuals who score higher on measures of neuroticism describe events in their lives as more stressful than individuals scoring lower on such measures (Marco and Suls 1993). Furthermore, controlling for these reporting effects, higher levels of neuroticism appear to be associated with greater numbers of stressful life events (Poulton and Andrews 1992). To explain such findings, some researchers have suggested that individuals who are prone to experiencing negative affect frequently generate stressful circumstances that then serve to maintain their negative orientations. As a result of these processes, the marriages of individuals scoring higher in neuroticism may develop in more challenging circumstances than the marriages of less neurotic individuals. Because challenging circumstances, such as unemployment and financial difficulty, have been shown to predict divorce, this may be another route through which the cumulative consequences of each spouse's personality contribute to marital success and failure.

3.2 Interactional Continuity in Marriage

In addition to its role in shaping the circumstances of the marriage, personality may also affect interpersonal processes occurring within the marriage. Spouses' expectations for each other, the behaviors they exchange during their interactions, and the way they interpret those behaviors, have all been associated with the stable dispositions of each spouse. Through these mechanisms, the personality of each member of the couple may give rise to self-fulfilling prophecies, such that stable personality traits predict spouses' feelings towards each other and thus lead spouses to act in ways that confirm or enhance those feelings.

Support for these ideas has been especially strong with regard to negative affectivity, that is, neuroticism. For example, spouses who are higher in negative affectivity tend to make less charitable attributions for

their partners' negative behaviors. That is, these spouses are more likely to hold their partners responsible for negative behaviors, whereas spouses who are lower in negative affectivity are more likely to excuse their partners for such behaviors (Karney et al. 1994). Perhaps as a consequence, among newlywed couples, negative affectivity is associated with marital satisfaction, such that spouses who are higher in negative affectivity are likely to evaluate the marriage as a whole more poorly than spouses who are lower in negative affectivity (Karney and Bradbury 1997). The stable tendency to experience negative affect thus appears to affect spouses' interpretations of the marriage at multiple levels, leading to partners that are perceived as less sensitive and marriages that are perceived as less rewarding.

The effects of each spouse's personality are not merely intrapsychic, however. In established marriages, the negative affectivity of husbands is associated with the marital satisfaction of their wives, such that the wives of husbands who are higher in negative affectivity tend to be less satisfied with the marriage, controlling for their own level of negative affectivity (Karney et al. 1994). One way that the personality of one spouse may affect the satisfaction of the other is through the effects of personality on the behaviors that spouses exchange during their interactions with each other. Indeed, in established marriages, neuroticism is associated with couples' problem-solving behavior such that more neurotic spouses report feeling more negative than less neurotic spouses immediately after an attempt to resolve a marital problem (Geist and Gilbert 1996). Furthermore, observational coding of spouses' behavior indicates that more neurotic wives express more negative emotions during conflict discussions. Given that the quality of couples' problem-solving behaviors predicts stability and change in the quality of the marriage over time (Karney and Bradbury 1997), the link between neuroticism and marital interactions may be one way that the personality of an individual may influence the development of marital quality for a couple.

4. Future Directions

Although research on the interactional consequences of personality has focused almost exclusively on behavior during marital problem-solving interactions, personality may play an even more prominent role in the way spouses solicit and provide each other with social support. To the extent that personality, and in particular negative affectivity, affects the way spouses treat each other and the nature of the stressful events they encounter, then research on the provision of social support in response to stressful events would be a direction for future research that promises to

integrate the cumulative and interactional consequences of personality in marriage.

Personality and Risk Taking

There is a long-standing and persistent belief that risk taking is a stable personality trait, often referred to as risk attitude. The belief implies that a given individual will take similar risks across a range of situations and that some people will be more risk-averse (or more risk-seeking) across situations than others. The article reviews different definitions of risk attitude that show cross-situational consistency to varying degrees. Sect. 1 shows that risk attitude defined within the expected utility (EU) framework varies greatly across situations as a function of decision content and outcome framing. Sect. 2 describes a more promising conceptualization of risk taking, within a risk-value framework. It models risk taking as a function of (a) decision makers' perception of the riskiness and value or return of different courses of action, and (b) their attitude towards perceived risk, i.e., their willingness to trade off (perceived) risk for return. Two individuals might differ in their recreational pursuits, for example, either because they assess the relative risks of skydiving, bungee jumping, and playing poker very differently (based on past experience, person A may perceive playing poker to be riskier than skydiving and thus choose to go skydiving out of risk aversion—a negative attitude toward risk, while person B may perceive playing poker as the less risky option and engage in it, also out of risk aversion) or, whether their risk perceptions agree or not, because they have different attitudes toward risk as they see it (with person C and D agreeing on the greater risk posed by skydiving, but person C being attracted by this risk and thus taking it on, and person D being repelled by it and thus choosing to play poker instead).

When modeled within this framework (as described in Sect. 3), situational differences in risk taking turn out to result from differences in the perception of risk in different situations rather than differences in willingness to take on (perceived) risk, thus restoring credibility to the notion of attitude towards perceived risk (PRA) as a stable trait. Individual differences in PRA exist, but are smaller and less systematic than individual and group differences in risk perception. While the determinants of risk perception are relatively well known at this point (see *Risk: Empirical Studies on Decision and Choice*; *Risk: Theories of Decision and Choice*) not much is known about the determinants of PRA. Personality differences in variables known to be

related to risk taking seem to have their effect via differences in risk perception, as described in Sect. 4.

1. Domain and Framing Effects on Risk Taking

In the EU framework, the dominant normative model of risky decision making, the term 'risk taking' is used to characterize choice patterns. Choice of a sure outcome over a lottery with equal expected value is modeled by a concave utility function and described as risk-averse; choice of the lottery is modeled by a convex utility function and described as risk-seeking. Despite the fact that risk taking simply describes the curvature of the utility function that is derived from a series of choices, 'those who coined the term *risk aversion* had in mind the psychological interpretation that someone who prefers the expected value of a gamble over playing the gamble *does not like to take risks*' (von Winterfeldt and Edwards 1986, p. 256). Popular as well as managerial folklore tends to interpret risk taking as a personality trait.

Bromiley and Curley (1992) review the evidence for risk taking as a personality trait, i.e., as a preference for risk that is stable across situations, and find it lacking. Risk taking seems to be influenced jointly by the situation and characteristics of the decision maker. Decision domains in which the same person often shows different degrees of risk taking include games of chance/gambling, financial investing, business decisions, health decisions, recreational choices, social choices, and ethical decisions (MacCrimmon and Wehrung 1986, Weber et al. 2000).

Modeling risk taking within EU theory and defining risk attitude as the curvature of a utility function thus is clearly problematic for the notion of risk attitude as a personality trait. Attempts to restore cross-situational consistency to the construct of risk attitude by factoring differences in marginal value (e.g., the incremental value of an additional dollar or an additional life saved) out of the utility function (see *Risk: Theories of Decision and Choice*) were not successful (Keller 1985, Weber and Milliman 1997).

Prospect theory (Kahneman and Tversky 1979) generalizes EU by postulating different utility functions for outcomes that are framed as gains as opposed to losses. When outcomes are framed as gains, choices tend to be risk-averse; when the same outcomes are framed as losses (relative to a higher reference point), choices tend to be risk-seeking, further complicating the interpretation of risk taking in the EU sense as a stable trait.

2. Risk Taking and Risk Perception

In the risk-value framework (see *Risk: Theories of Decision and Choice*), risk taking is a compromise between greed (value) and fear (risk). Risk-value

models in finance equate 'value' with the expected value of a risky option and 'risk' with its variance. Generalized risk-value models allow for a broader range of risk measures. *Risk: Empirical Studies on Decision and Choice* reviews evidence that risk is perceived differently by different individuals, cultures, or subcultures. Situational differences such as outcome framing also result in different risk perception (Mellers et al. 1997). As a result, apparent differences in risk taking may be the result of differences in the perception of the riskiness of the choice options, and not of differences in attitude towards (perceived) risk. Cooper et al. (1988) report, for example, that—contrary to managerial folklore—the characteristic that differentiates entrepreneurs from other managers is not a more positive attitude towards risk, but instead an overly optimistic perception of the risks involved. For an outside observer who perceives risk more realistically, entrepreneurs will thus appear to take great risks. However, when differences in risk perception are factored out, entrepreneurs—just as other managers—demonstrate a preference for tasks that they see as only moderate in risk (Brockhaus 1982).

3. Perceived-risk Attitude as a Stable Trait

PRA is a measure of the degree to which individuals find perceived risk attractive (or unattractive) and therefore will choose alternatives that carry greater (or less) risk, all other things being equal. Weber and Milliman (1997) examined its cross-situational consistency by asking commuters to choose between pairs of trains that had risky arrival times (that depended on making a connection that had a stated probability) and to judge which of the two trains was the riskier one. The two trains in each pair had arrival times with equal expected value but different variance. Some pairs of trains had only positive arrival times (faster or equal to current travel times), others had only negative arrival times (slower or equal to the status quo). There was little consistency in people's risk taking across the gain and the loss domain when risk taking was defined in the EU sense. Few commuters had preferences that resulted in utility functions that were either both risk-seeking (convex) or both risk-averse (concave). However, consistency across the two domains was very high when PRAs were compared. The majority of commuters were risk-averse in both domains, i.e., consistently chose the train in a given pair that they had judged to be the less risky of the two.

In another study, MBA students participated in two sessions of an investment game where they had to pick one of six stocks (described by standard financial indicators) in each of 10 investment periods, and had to rate the riskiness of the stocks at different points throughout each session (Weber and Milliman 1997).

In one session, participants lost money in most of the 10 periods, whereas in the other session they mostly made money. Choices were very different across sessions (with more switching between stocks in the failure session), as were the ratings of the riskiness of the six stocks. However, over 80 percent of investors had the same PRA in both sessions, with three-quarters consistently investing in stocks that they perceived to be less risky and one-quarter consistently investing in stocks that they perceived to be more risky.

In a cross-national study, Weber and Hsee (1998) obtained risk judgments as well as minimum buying prices for risky financial investment options from respondents in the USA, Germany, the People's Republic of China, and Poland. Both risk judgments and buying prices showed significant cross-national differences, with Americans perceiving the most risk and Chinese paying the highest prices. However, after differences in risk perception were taken into consideration, the proportion of individuals who were perceived risk-averse or perceived risk-seeking were not significantly different in the four countries, with the majority again being perceived risk-averse, and only a small percentage in each country being perceived risk-seeking.

4. Personality, Risk Perception, and Perceived-risk Attitude

Some psychologists have questioned the assumption of finance models that people will and should strive to minimize risk, arguing instead that people's ideal point for risk or uncertainty could differ, either as a personality difference (Lopes 1987) or as a situational difference (Weber and Kirsner 1997). Ideal-point models (Coombs 1975) assume a person will perceive the riskiness of an alternative as the deviation between the alternative's level of uncertainty or unpredictability and the person's ideal point on the uncertainty continuum. Perceived risk of an alternative with a high objective level of uncertainty would be high for a person with a low ideal point, but low for a person with a high ideal point. Individual differences in ideal points for risk and uncertainty have been measured by the construct of sensation seeking (Zuckerman 1979), which seem to have some biological basis (Zuckerman et al. 1988) and vary with age and gender (see *Sensation Seeking: Behavioral Expressions and Biosocial Bases*). Bromiley and Curley (1992) report evidence linking sensation seeking to behavioral correlates that include greater risk taking, especially in the health/safety and recreational domain. Weber et al. (2000) also report high positive correlations between sensation seeking and its subscales in several content domains, with especially high correlations between the thrill-and-adventure-seeking subscale and recreational risk

taking and the disinhibition subscale and ethical risk taking. Consistent with the predictions of ideal-point models, the path by which differences in sensation seeking seem to affect risk taking appears to be differences in the perceptions of risk, rather than differences in attitude towards perceived risk. In other words, groups known for high levels of sensation seeking (e.g., teenage boys) seem to take large risks because they perceive the levels of risk to be smaller than other groups, and not because they cherish (perceived) risk to a greater extent.

5. Summary, Caveats, and Future Directions

The current research consensus suggests an interactional model of risk taking (e.g., Sitkin and Weingart 1995) in which situational characteristics as well as person-centered characteristics jointly influence risk taking. Situational constraints include the content domain of the risky decision as well as contextual variables such as outcome framing and aspiration levels (Lopes 1987). Person-centered characteristics include age, gender, culture, and personality. These variables influence risk taking mostly by changing people's perception of the riskiness of decision alternatives, rather than by affecting their willingness to take on more or less risk.

Because of the domain specificity of risk taking, measures of risk attitude that employ choice situations across a range of content domains (e.g., the Choice Dilemmas Questionnaire of Kogan and Wallach 1964) have little predictive validity. Domain-specific scales of risk taking, that help to diagnose apparent differences in risk taking into differences in either risk perception and/or PRA have recently developed (Weber et al. 2000). Future research will provide additional insights into the complex interactions between personality and situation that have been explored for a range of other traits (Mischel 1999) with respect to risk taking. A combination of task analysis and theory about the reasons for risk taking and its cognitive and emotional constraints should lead to the development of gender-, culture-, and domain-specific risk taking profiles, that predict level of risk taking in a situation- and person-contingent fashion.

E. U. Weber

Personality and Social Behavior

The link between personality and social behavior can be approached in two ways. The first question is to what extent social behavior is caused by personality

factors. The second question is what effects social behavior has on personality. Both questions have proven surprisingly difficult for social scientists to answer.

Personality refers to the stable traits and dispositions that characterize individual people. In simplest terms, social behavior has two possible causes: personality and the situation. Although it is tempting to assign everything inside the person to personality and everything outside to the situation, the reality is somewhat more complex, because external factors (such as being insulted by others, an emergency, or an opportunity) may create temporary internal states. Personality is thus usually reserved to the relatively stable aspects of the person, as opposed to temporary states. One handy test is what aspects of the person remain the same when he or she moves from one situation to another. Personality consists of those aspects.

1. Mischel's Challenge to Personality

The view that social behavior derives from personality is deeply rooted in common sense and traditional views. People are widely believed to have stable personality traits that account for readily discernible patterns in their behavior. Indeed, the very concept of personality is usually understood in terms of consistency. That is, people are supposedly consistent in their motivations and actions.

Walter Mischel (1968) challenged this alleged consistency of personality in an influential book. Mischel proposed that if personality were composed of a stable, consistent set of traits, then psychological measures of traits should effectively predict social behavior quite strongly. From a review of published research studies, however, he concluded that personality traits have not been shown to have strong effects on behavior. Instead, he found that the correlations between traits and behaviors were usually small: Typically the correlation was found to be 0.20 to 0.30 out of a maximum possible 1.00. He used the term 'personality coefficient' to refer to the small correlations that were typically found.

Mischel therefore concluded that the situation is far more powerful than personality as a cause of social behavior. Following the standard statistical practice, he pointed out that a correlation of 0.30 accounts for only 9 percent of the variation in behavior, leaving the other 91 percent to the situation. Put simply, the situation was 10 times as powerful as personality in determining behavior.

This view was immediately recognized as challenging the view that personality is an important cause of social behavior. Psychologists were not the only ones to have believed in personality, for the general public has also had a long and firm belief in personality.

Mischel's colleague Lee Ross (1977) coined the term 'fundamental attribution error' to refer to people's tendency to interpret someone's behavior as caused by that person's personality traits and to underestimate the importance of the situation in causing behavior. For example, people who observe an angry outburst will tend to conclude that the angry person has a hostile or aggressive personality while in fact the true cause of the angry outburst is likely to be a bad day, a provocation, a frustration, or some other cause rooted in the immediate situation. A well-known work by Jones and Nisbett (1971) pointed out that people tend to attribute their own behavior as caused by their situation (e.g., 'I was only following orders' or 'I was just reacting to what you did'), whereas they interpret other people's behavior in terms of personality traits.

Mischel's book and his striking conclusions had a major impact on psychology. One implication was that psychologists should focus on analyzing the situation rather than the individual personality in order to be able to understand and predict behavior. Social psychologists, who specialized in studying the power of situations, embraced this conclusion to the detriment of personality psychologists. This attack on personality coincided with a period of rapid growth in US psychology departments, and as a result many universities hired social psychologists rather than personality psychologists, with the result that social psychology continues to be a much larger field than personality even several decades later.

A recent analysis of the controversy by Funder (1997) summarized Mischel's argument as having three essential parts. First, a review of the literature shows that there is an upper limit to how well one can predict someone's behavior from one situation to the next, and this upper limit is small (a correlation of around 0.20 to 0.30; Nisbett 1980 later revised this upward to 0.40). Second, situations are more important than traits in explaining behavior. Third, it is no use to measure personality, and the common and traditional view of people as consistent, personality-driven beings is wrong.

2. Defending Personality

Personality psychologists gradually came forward to defend their field of study and the value of their work against Mischel's critique. One important point was that the correlations of 0.20 to 0.40 are not trivial and can in fact contribute useful knowledge. A correlation of 0.40 means that a prediction of behavior would be right 70 percent of the time (compared to 50 percent by chance).

Moreover, the conclusion that situations are much more powerful than personality traits does not stand up under scrutiny. Funder and Ozer (1983) analyzed the power of situational variables to predict behavior,

using several classic social psychology experiments on cognitive dissonance and bystander reactions to emergencies. Funder and Ozer (1983) found that the well-known effects of these situational factors were about the same size (between 0.30 and 0.40, when converted to correlations) as Mischel's personality coefficient. In other words, trait and situation have about equally powerful effects; it was simply not true that the situation was 10 times as powerful as personality.

Another important point was that the seeming weakness of personality traits for predicting behavior was partly due to the way psychologists did their research. Typically they would use a standard questionnaire to assess some general trait, such as helpfulness, and then they would correlate it with how helpful the person was in a specific situation (such as how the person responded to a request to donate blood). The problem with such designs is that only a single, context-specific behavior was measured, which might not match up well with a broad trait. In contrast to that procedure, some researchers began aggregating multiple behaviors. Thus, instead of only measuring whether the person acceded to one request to donate blood, one could combine many different helpful behaviors, such as taking care of sick friends, giving directions to strangers, volunteering to help on a hotline, donating money, befriending disadvantaged children, helping friends with chores, and assisting someone with schoolwork. Epstein (1979a, 1979b) found that aggregating behaviors in that way enabled traits to predict behavior at a level of over 0.80 in some cases, thus far more successfully than the 0.3 coefficient derived by Mischel.

The success of aggregation is revealing about how personality is linked to social behavior. It shows that personality traits can predict behavior in general with good success. They are, however, much less successful at predicting single behaviors. To know someone's personality is therefore to be able to predict how that person will behave in many situations, but it remains much harder to say how a given person will react on a particular occasion.

3. Traits and Metatraits

Another possible reason for the seeming weakness of the link between personality and behavior is that not all personalities are composed of the same kinds of traits. Bem and Allen (1974) proposed that some people are more consistent than others with respect to certain traits. Including inconsistent people in a research project will inevitably weaken the results. For example, Bem and Allen (1974) asked people whether they were consistent or inconsistent on the dimension of sociability. One person might be consistently high in sociability, or consistently medium, or consistently low. Someone else might be inconsistent, in the sense

that the person acts in a highly sociable manner one day but in an unsociable or even antisocial way the next. Bem and Allen computed the correlation between trait sociability score and a behavioral measure of sociability twice: once for the people who said they were consistent, and once for the inconsistent ones. The correlation was much higher for the people who were consistent.

The implications of Bem and Allen's idea are potentially profound. For some people, the trait of being sociable versus unsociable is a stable, consistent aspect of personality, but for others it is not. One theme in personality psychology is the attempt to measure traits, but perhaps some people should not be measured on some traits. The question 'How sociable are you?' may be relatively meaningless for some people, because the answer would fluctuate from day to day and from one situation to another. For the latter, apparently, their personality lacks anything that could be described as a trait level of sociability. Baumeister and Tice (1988) used the term 'metatrait' to describe this pattern. A metatrait is literally the trait of having (or not having) a trait. For traited people, behavior will tend to be consistent. For untraited people, behavior may vary widely even within seemingly similar situations.

The idea of metatraits poses a serious challenge to both the measurement and the conceptualization of personality. Several methods have been proposed to ascertain whether people are traited on a given trait or not. There is ample evidence that the very same measures yield much stronger results for traited as opposed to untraited people (Baumeister and Tice (1988, see also Britt and Shepperd 1999). Yet other experts have proposed that these measures could potentially have statistical problems (e.g., Tellegen 1988), and there is not yet a general consensus on the best way to deal with these.

Still, the idea that people differ in their level of consistency is promising, and eventually it may turn out to be a crucial aspect of the link between personality and social behavior. The implication is that personality contains something that makes the person's behavior consistent, and that some personalities do not have whatever that is. Although Bem and Allen (1974) and most subsequent researchers have assumed that different people are traited on different traits, Snyder (1974) proposed that some people are simply more consistent than others across all traits. He developed a measure of self-monitoring that sought to assess how much each person changes his or her behavior from one situation to another. The term 'self-monitoring' refers to the monitoring of situational cues and altering one's own behavior accordingly. People who are high in self-monitoring are defined as being alert to circumstances and quick to change their behavior so as to do what might work best in any given situation. In contrast, people who score low in self-monitoring tend to act based on their inner feelings

and values regardless of the situation. Hence low self-monitors will be more consistent across different situations, whereas high self-monitors will tailor their behavior to each situation and exhibit less cross-situational consistency.

4. Different Situations

Two other ways of understanding the link between personality and social behavior focus on differences between situations. One of these emphasizes simply that different situations vary in their power to dictate behavior. A strong situation can override personality traits, so that nearly everyone will act the same way. In contrast, a relatively weak situation will allow behavior to be driven by personality.

Research on behavior in emergencies has provided a good illustration of this approach. Darley and Latané (1968) investigated the question of whether bystanders will come to the aid of a victim in an emergency. They found that when bystanders are alone and believe themselves to be the only ones who can help the victim, they are quite likely to act. In contrast, when there are many bystanders, each is likely to think that it is someone else's responsibility to take action, and so each will tend to do nothing. Across a series of studies, they measured an assortment of personality traits, but none of these traits predicted behavior. They concluded from their research that personality is largely irrelevant to how people respond in emergencies (see Latané and Darley 1970). They suggested that emergency situations are both powerful and unusual, and so few people develop habits or traits about how to deal with them.

The conclusion that personality is irrelevant to emergencies came under criticism from personality researchers. They proposed that the original researchers had simply used extremely powerful versions of the emergency situation, with either no one else available to help or a great many people. What about when there are only one or two other people who might help? When the emergencies were set up with just one or two other bystanders, the response rate moved to the intermediate level of 50 percent, and personality traits were quite effective at predicting which people would respond (Siem and Spence 1986, Tice and Baumeister 1985).

In short, situations do vary in how powerfully they exert pressure on people to respond in a particular way. When this power is high, there is little room for personality to make a difference. In contrast, when the power of the situation is low, personality can be decisive. This conclusion complements the metatrait view that some personalities are more strongly geared toward consistent behavior than others. An untraited person will generally respond based on the situation, whereas a traited person will act based on his or her

personality. Conversely, a powerful situation will dictate behavior, whereas a weak one will leave behavior to be determined by inner traits.

The second situation-based approach was put forward by Snyder and Cantor (1998). In this theory, situations are the primary determinant of behavior — but personality dictates which situations the person enters. For example, introverted people may avoid loud parties, and so their behavior does not come under the influence of the party atmosphere. Thus, personality and situations may operate in sequence rather than in direct competition for determining social behavior. Personality involves the grander role of how people set up their lives and how they make broad choices, whereas situations exert the immediate and short-term influence over how the person acts.

5. Behavior Shapes Personality

Although most research has focused on the question of whether personality determines social behavior, there has been some work on the complementary question of whether behavior shapes personality. To be sure, personality is defined as stable and consistent, so such change will be slower, smaller, and more gradual than changes in behavior. Yet few people believe that personality is utterly immune to change. A compilation of works by many experts on the topic of 'Can personality change?' yielded an emphatic answer of 'yes,' even though change was acknowledged to be difficult and slow in many cases (Heatherton and Weinberger 1994).

One of the possible models of personality change involves internalization. For example, young women do not magically develop maternal personalities, nor are these traits always visible during their youth prior to motherhood, but upon assuming the role of mother a woman may begin to change her behavior, and over time these new patterns of maternal behavior can become firmly established to the point that the woman's personality can be said to have changed to fit the role.

How does the internalization process operate? One important theory was proposed by Jones et al. (1981). These authors suggested that people's self-concepts contain a great deal of information that is not necessarily consistent or well-organized. When people are induced to act in a certain way, they begin to recall other behaviors that are consistent (and to ignore previous acts that would not be consistent). Eventually the self-concept shifts to accommodate these patterns of behavior, and then the personality itself follows suit. Fazio et al. (1981) asked people a series of loaded questions that were designed to get them to think about themselves as either extraverted or introverted (e.g., 'What things would you do to liven up a dull party?' versus 'What do you dislike about loud,

crowded parties?"). Their self-concepts shifted accordingly. Later, when they were left alone with a stranger, their behavior followed from the newly induced self-concept, which implies that there was at least some lasting change in their personality. Specifically, the people who had been led to think of themselves as introverts sat quietly and did not talk with the stranger, whereas the people who had been led to think of themselves as extraverts were more likely to strike up a conversation with the stranger.

The importance of the social dimension of behavior emerged in subsequent work. Tice (1992) showed that people only internalize behaviors that are witnessed by other people. That is, when people gave their answers to another person in an interpersonal setting where another person heard them, they showed evidence of personality change. In contrast, when they gave their answers confidentially and anonymously by speaking into a tape recorder while alone, they showed no sign of internalization. The implication is that secret and private behaviors do not lead to internalization as much as do public, interpersonal behaviors. The social context—specifically, whether other people are there to witness the behavior—is decisive as to whether behaviors lead to inner change.

The practical side of this can be seen in the practices used by cults and other organizations that seek to 'brainwash' or otherwise bring about fundamental changes in people's values, motives, and other aspects of personality. Attempts to effect such change by bombarding the person with messages or influence while the person sits there passively have not proven effective. Nor is it apparently enough to get the person to comply in a private or anonymous fashion. Rather, success at brainwashing depends on inducing the person to comply actively and publicly. New recruits to a religious cult may, for example, be induced to speak out in front of the group about their new commitment to the cult or even to approach strangers to tell them about the cult, ask for donations, distribute literature, and the like. Such public actions help cement the person's commitment to the cult and bring about the inner change that the group seeks.

6. *Interactionism*

Although the intellectual debate has been cast in terms of whether the trait or the situation is the main cause of behavior, this is merely a matter of emphasis: Most experts believe in interactionism, which is the doctrine that behavior is an interactive product of the person and the situation (see *Interactionism and Personality*). Put another way, hardly anyone believes that traits are so powerful that people will always behave the same way regardless of situation, nor does anyone really believe that there are no meaningful differences among individuals.

The interaction between person and situation is implicit in several of the formulations already noted, such as the idea that personality dictates the selection of particular situations, and then the situations guide actual behavior. An explicit interactionism would assert that any approach is doomed if it focuses on merely the person or merely the situation. A crowded, noisy party will make some people mingle happily with the crowd and enjoy shouted discussions with groups of people, while others retreat to search for a quiet place where they can talk at length with a single person. Likewise, a major upcoming test will strike some people as a threat, making them so anxious that they avoid studying, whereas others will embrace the test as a challenge and prepare to do their best. Thus, seemingly identical situations elicit very different behaviors from different people, depending on their personalities.

Modern statistical techniques allow the observations of human behavior to be divided into three parts. Trait and situation each claim a share, and the interaction (between trait and situation) gets the third share. The trait share refers to how much behavior is affected directly by personality, independent of the situation (and thus consistently across different situations). The situation share involves how much all different people will give essentially the same response to the situation. Last, the interaction encompasses ways that the same situation affects different people differently.

There is unfortunately no general principle or agreement as to which of these three shares is generally the largest. It appears that some situations are quite powerful in affecting everyone the same way. Other situations are relatively weak (such as unstructured situations), and traits exert considerable influence there. Interactions do not always occur, but they are common and often generate the most interest, insofar as different people react in reliably different ways.

7. *Future Directions*

At present, it appears that personality psychology has successfully survived the crisis provoked by Mischel's (1968) critique, although some effects linger (such as the smaller size of personality psychology faculty). Instead of looking at personality and situation as competing against each other to explain behavior, the current emphasis is to understand how they interact and complement each other. A priority for the next generation of research is to assess the several models (described above) for possible interactions, such as differential traitedness, personality dictating entry into situations and situations being the proximal causes of behavior, and differential power of situations.

Another reason to expect increasing rapprochement between research programs focusing on personality

and programs focusing on situational causes is contained in the logic of scientific development. As in most fields, broad generalizations and sweeping general principles are likely to be identified first, whereas later generations have to study more fine-grained and subtle effects. The behavioral principles that are generally true for everyone were likely identified relatively early in psychology's scientific development. Subsequent generations of researchers will therefore have to focus more on principles that apply only to certain people, and these attempts to understand how situations affect particular groups will require a greater sensitivity to individual differences and a greater integration between personality and situational factors.

The study of how situations and specific experiences produce lasting changes in personality remains wide open for new ideas and creative research. The question of how personality changes is likely to be of increasing importance in the coming decades for many reasons, including the wish to facilitate child development toward desired personality outcomes, the increasingly recognized need to offset the consequences of harmful parenting or other nonoptimal upbringing patterns, and in particular the wish to enable clinical psychology to bring about the desired changes in a reliable and lasting manner.

Personality Assessment

To assess personality is to characterize the enduring psychological qualities that contribute to the coherence and uniqueness of the individual person and to the differences among individuals. The task of personality assessment commonly is construed in terms of the measurement of quantifiable personality variables. However, personality assessment may include both quantitative and qualitative techniques.

The set of methods that psychologists have employed to assess personality is highly diverse. There are two main reasons for this. One is that assessors have held varying beliefs about the nature of personality itself. The twentieth century witnessed a variety of formal theories of personality. These theoretical positions have guided assessors' decisions about the aspects of personality to assess and the procedures to use to assess them. Diversity in personality theory thus has fostered a corresponding diversity in assessment techniques. The second reason is that investi-

gators may assess personality with different goals in mind. One may aim, for example, to describe normal variations in personality in the population at large; to diagnose psychopathology suffered by a small subset of the population; or to obtain a detailed portrait of the psychological structures and dynamics that characterize a particular individual. Different goals commonly require different assessment methods. The methods that contemporary investigators employ are reviewed below, following a history of the field.

1. History

In a general sense, to assess personality is to evaluate the individual in a formal manner. Personality assessment, then, is as old as is the development of formal schemes for characterizing persons. Two early schemes are found in ancient Greece. The *Corpus Hippocraticum* introduced the notion that variations in four bodily humors (blood, phlegm, yellow bile, and black bile) determine one's predominant psychological temperament (sanguine, melancholic, choleric, and phlegmatic). Theophrastus, a disciple of Aristotle, provided a series of character sketches of common personality types, each defined according to a moral attribute (the liar, the adulterer, etc.). The differences between these approaches—one examining biological constitution and providing a simple system for characterizing individual differences, and the other focusing on social behavior in the moral domain and providing a more differentiated set of descriptors—interestingly foreshadows variations within the contemporary field.

The more recent centuries witnessed attempts to link personality to biological anatomy. Investigators measured anatomical features in an effort to identify underlying causes of overt psychological qualities. These efforts included the eighteenth to nineteenth century work of Lavater, who interpreted facial features; the 'organology' of Gall and 'phrenology' of Spurzheim, both of whom assessed variations in the anatomy of the skull; and the work of Lombroso, who assessed physical features that purportedly were markers of criminality. These efforts, of course, proved to be of little lasting value.

A more sophisticated conception of assessment was found in the efforts of Charcot, Janet, Freud, and Jung to diagnose the causes of psychopathology. Freud's free association technique, for example, was not only a therapeutic treatment but an assessment tool. Whatever the merits of these efforts, however, they failed to meet applied psychologists' need for efficient assessments that could be administered easily to relatively large populations.

Modern approaches to personality assessment can be traced to the late-nineteenth and early-twentieth century efforts of Galton and Binet to assess intelligence. Their standardized, paper-and-pencil assessments of individual differences in intellectual abilities

provided a model for the standardized assessment of individual differences in personal styles, preferences, and behavioral tendencies. The first paper-and-pencil standardized personality inventory was the Woodworth Personal Data Sheet, which was developed during World War I to screen from the US armed forces individuals suffering from psychological disorders. Thanks heavily to their ease of administration, standardized self-report tests proved to be the most commonly employed personality assessment method throughout the remainder of the twentieth century.

A noteworthy alternative to paper-and-pencil assessment was developed during World War II by psychologists at the US Office of Strategic Services, working under the direction of Harvard psychologist Henry Murray. To screen candidates for participation in risky missions, this group assessed candidates' behavior in artificially constructed situations that contained the same types of challenges (e.g., solving practical engineering problems, displaying leadership in a group) that one might face on an actual mission. Such *in vivo* behavioral assessments can be of much predictive value. However, they are much more cumbersome and costly than paper-and-pencil self-reports, and thus are used much less frequently.

Finally, two theoretical developments in the 1950s and 1960s proved to be of historical importance to the field. One was the development of the concept of *construct validity* (Cronbach and Meehl 1955). Construct validity is concerned with the degree to which an assessment tool adequately measures a hypothesized psychological construct, as that construct is understood within a given theoretical framework. Determining the validity of a test generally involves gauging the degree to which that test predicts external criteria to which the associated construct should be related. A valid self-report test of conscientiousness, for example, would be one that adequately samples the domain of conscientious behaviors and predicts external criteria involving conscientious actions such as adhering to social norms and controlling impulses.

The second development was a paradigm crisis in the field of personality assessment in the late 1960s. Although the crisis had many sources, a critique by Mischel (1968) was particularly influential. Mischel questioned whether assessments of decontextualized or 'global' personality constructs predict specific behaviors to which they are conceptually related. His review indicated that global personality measures commonly either fail to predict behavioral criteria or predict so little of the variance that they are of little practical use. His critique prompted divergent reactions. Some tried to improve the measurement of global psychological characteristics. Others developed personality theories and associated assessment tools that were not based on global trait variables. These theoretical alternatives were, instead, grounded in the analysis of basic cognitive and affective processes, and the social contexts that activate these psycholo-

gical mechanisms. These ‘social–cognitive’ theories aimed to account for both trait-like consistency and situation-to-situation variability in behavior (see *Personality Theory and Psychopathology*).

2. Distinctions among Contemporary Approaches to Personality Assessment

The diversity of contemporary assessment tools can be organized according to a set of distinctions that differentiate alternative assessment efforts.

2.1 Targets of Assessment

One distinction concerns the target of personality assessment; that is, what it is that one is trying to assess. The most basic differentiation separates (a) the assessment of overt, surface-level tendencies in experience and action from (b) the assessment of internal personality structures and dynamics. Phrased simply, one may assess either phenotypic tendencies or genotypic psychological systems that causally contribute to those tendencies.

Whether one is assessing surface-level tendencies or internal psychological systems, one still must choose the precise tendencies or systems to target. These decisions generally are guided by broad theoretical principles about the nature of personality. With respect to surface-level phenotypes, the most common choice is to assess mean-level behavioral tendencies. Assessors commonly compute people’s average tendency to display a particular type of behavior by aggregating together behavioral reports from diverse social contexts. This choice reflects the thinking of trait theories of personality, which view average tendencies in action as the defining expression of personality. In contrast, others caution that an assessment of mean-level tendencies is a necessary but insufficient step. It is insufficient because other features, such as variation in action across contexts (Mischel and Shoda 1995) or time (Larsen 1989), also distinguish individuals from one another. The assessment of contextual variation in action is consistent with social–cognitive theories of personality (Bandura 1986, Cervone and Shoda 1999), as detailed in Section 3.2.

Regarding the underlying genotypes, different theories again suggest different targets of assessment. Psychodynamic views explain behavior in terms of internal psychic conflicts that involve material of which persons are not consciously aware. Assessment thus must target these nonconscious psychological systems; projective tests such as the Rorschach inkblot test and the Thematic Apperception Test are designed for this purpose (see *Projective Methods in Psychology*). Social–cognitive theories contend that the core features of personality are cognitive capabilities

through which people acquire social skills, reflect upon themselves, evaluate their actions, and regulate their behavior and emotional experience in accord with personal goals and standards for performance (Bandura 1986) (see *Social Cognitive Theory and Clinical Psychology*). This view dictates that assessments target an interacting system of cognitive and affective mechanisms (Cervone et al. 2001). Both psychodynamic and social–cognitive theories anticipate that there may be complex, nonlinear relations between underlying psychological systems and overt behavioral patterns. In contrast, some trait theories of personality propose that internal personality structures and overt behavior are related in a relatively direct, linear manner. Personality is construed as a small set of inherited trait structures (e.g., conscientiousness, extraversion), each of which fosters a characteristic mean level of phenotypic thoughts, feelings, and actions (e.g., conscientious acts, extraverted acts; McCrae and Costa 1996). Finally, some theorists study the role in personality functioning of personal narratives that individuals construct over the course of life (McAdams 1996). Their work suggests that personality assessment should include procedures (e.g., oral interviews or written narratives) to assess individuals’ life stories.

2.2 Nomothetic vs. Idiographic Assessment

A second distinction involves overarching strategies of assessment. One strategy is to focus on an individual person and determine the potentially unique constellation of psychological variables that best characterizes that individual. Another is to focus first on the variables, and to seek a set of personality variables and associated assessment procedures that can be used to characterize the personality of any and all individuals. The former approach is an ‘idiographic’ strategy (from the Greek *idios*, referring to personal, private, and distinct characteristics), whereas the latter approach is ‘nomothetic’ (from the Greek for law, *nomos*, used here to refer to the search for universal scientific laws). A typical nomothetic strategy might use standardized tests to determine individuals’ relative standing on one or more individual-difference variables. Idiographic assessment might involve interviews, unstructured self-descriptions, or biographical analyses of an individual’s life.

Personality assessment may blend nomothetic and idiographic procedures. For example, one may have the same assessment goals and employ the same general testing procedures with all individuals. However, the exact content of the test items one employs may vary from person to person. Kelly’s (1955) Role Construct Repertory test is a classic example of a test that combines nomothetic procedures with idiographic content. The assessor’s goal is always to identify the ideas, or constructs, that people use to understand their world. The testing procedure is

always one in which test takers are asked to indicate how a set of target persons is similar or different from one another. The exact content of the test items, however, varies idiographically. Each test taker provides a personal list of individuals who are of importance to him or her. This personalized list then comprises the list of target persons employed in the test. Contemporary assessments of belief systems and social-cognitive processes commonly mix idiographic and nomothetic methods in this manner (Caprara and Cervone 2000).

In practice, personality assessment has been dominated by the use of nomothetic procedures. The most commonly employed assessment instruments, such as the Cattell 16 P.F. Inventory, the Eysenck Personality Questionnaire (EPQ), the Minnesota Multiphasic Personality Inventory (MMPI), or the revised NEO personality inventory (NEO-PI-R), are nomothetic devices (see *Minnesota Multiphasic Personality Inventory (MMPI)*). Assessment consists of the administration of a standardized test that is used to rank individuals on a set of individual-difference dimensions.

2.3 Sources of Data

Whether one is employing a nomothetic or idiographic strategy, another question faced by the personality assessor is the source of data to draw upon. Block (1968) has drawn useful distinctions among alternative data sources; the following section modifies and elaborates upon his distinctions in light of contemporary research developments.

One can delineate at least seven sources of data that may be used in personality assessment

(a) *Behavioral Observations in Naturalistic Settings* are direct observations of a person's everyday behaviors, or the analysis of biographical records (e.g., school attendance records, records of legal infractions) that provide an objective index of such behaviors.

(b) *Behavioral Observations in Experimentally Constructed Settings* are observations of a person's behavior in situations designed by a researcher to constitute a context that is relevant to a personality construct or constructs under study. The test taker's reactions in that context are interpreted as indicators of the construct. Although the use of experimentally constructed settings has the advantage of greater experimental control, it also has a significant disadvantage. Personality characteristics often reveal themselves in the way people select environments; that is, in their choices to enter some settings and avoid others. Assessment procedures that confront all individuals with a fixed set of circumstances are insensitive to the influence of personality factors on the selection of environments.

(c) *Explicit Self-reports* ask people to describe their typical behaviors, thoughts, feelings, or personal

characteristics. This is most commonly done through standardized multi-item tests, although explicit self-reports also may involve less structured techniques such as the writing of self-descriptive narratives.

(d) *Implicit Self-reports* are designed to tap beliefs or self-evaluations of which individuals may not be explicitly aware. For example, reaction-time techniques can reveal the degree to which individuals associate concepts with one another; an implicit test of self-esteem might use reaction-time measures to determine how strongly the concept of 'self' is linked to concepts of positive vs. negative emotional tone (Greenwald and Banaji 1995).

(e) *Observer Reports* are assessment procedures in which peers, family members, or other persons familiar with an individual are asked to evaluate their typical behaviors, feelings, or personal characteristics.

(f) *Psychophysiological Indices* include any of a wide variety of indicators of neural or biochemical systems that directly bear upon personality functioning and psychological differences among individuals. For example, electrophysiological measures are used to assess individual differences in cortical brain activity that may be a biological basis of overt individual differences in extraversion (Geen 1997).

(g) *Cognitive Indices* are assessments of the content or organization of a person's knowledge about themselves and the world. Many of the most important differences among individuals involve differences in knowledge and beliefs systems. A diverse set of tools, many deriving from the study of social cognition, have been employed to assess enduring individual differences in the content, complexity, and organization of knowledge structures that underlie personality functioning and individual differences (Caprara and Cervone 2000).

2.4 Comprehensiveness of Assessment

A final distinction concerns the comprehensiveness of personality assessment. Assessors sometimes wish to obtain a relatively complete portrait of the dispositional tendencies or underlying psychological dynamics that characterize an individual. Alternatively, one may desire merely to tap one or two personality variables of interest. The term 'personality assessment' commonly is applied to both comprehensive assessment efforts and measures of individual personality variables.

3. Illustrative Assessment Strategies: Five-factor Theory and Social-cognitive Theory

The conceptual distinctions drawn above are somewhat abstract. A more concrete understanding of alternative personality assessment strategies can be obtained by considering some examples of theory-

driven assessment. Two examples are considered here; namely, the personality assessment procedures that derive from five-factor theory (McCrae and Costa 1996) and social-cognitive theory (e.g., Bandura 1986, Mischel and Shoda 1995, reviewed in Cervone and Shoda 1999).

3.1 *Assessing Individual Differences in Global Dispositional Tendencies; The 'Big Five' or 'Five-factor' Model*

As noted above, the most common approach to personality assessment is to rank individuals on nomothetic individual-difference dimensions. The dimensions commonly represent global surface-level tendencies; that is, average tendencies to display behaviors that are representative of a given dispositional category. In a comprehensive assessment effort, individuals are ranked on a system of n individual-difference dimensions. The individual's personality is then represented as a point in n -dimensional space.

A primary question that arises is: What are the n dimensions? What set of dimensions is necessary and reasonably sufficient to capture individual differences in the population? A corollary question is methodological: How can one identify these dimensions? On the latter question, there has long been consensus. Investigators conduct factor analyses of the dispositional tendencies of large populations of individuals. The resulting factors then constitute the dimensions that form the core of personality assessment. Despite consensus on methods, on the former question there historically has been disagreement. Investigators in the mid-twentieth century proposed factor-analytic structures containing as many as 16 and as few as two dimensions. A major development in the 1980s and 1990s is that investigators achieved substantial consensus on the number and the nature of the factors required to assess phenotypic individual differences. Consensus centered on a five-dimensional trait taxonomy known as the big five (John and Srivastava 1999) or five-factor (McCrae and Costa 1996) model. The factors represent global individual differences in (a) extraversion or energy, (b) emotional stability or neuroticism, (c) conscientiousness, (d) agreeableness, and (e) openness to experience, particularly novel intellectual or cultural experiences. (Some interpret the fifth factor as being closer to intellect than to openness.) This five-dimensional structure has been identified in both self-reports and observer-reports, in assessment using both trait adjectives and items from professional personality inventories, and in both English (the model's language of origin) and other Indo-European and non-Indo-European languages.

The five-factor model provides an appealingly simple solution to the problem of assessing phenotypic

tendencies. One merely plots people's average tendencies to exhibit actions indicative of each of five dispositional categories. Assessors also may seek more detailed information, such as people's tendency to display behaviors that are representative of narrower trait dimensions that are hierarchically related to the primary factors (in the way that sociability, for example, is hierarchically related to extraversion). Nonetheless, measuring the big five remains the core assessment task.

To some, the model also provides an appealingly simple solution to the problem of assessing causal genotypic structures. Although many proponents of the big five structure treat it merely as a descriptive model (Goldberg 1993), some suggest that it also is explanatory. In McCrae and Costa's (1996) five-factor theory, the factors are construed as 'dimensions of individual differences in tendencies to show consistent patterns of thoughts, feelings, and actions ... (and) also ... a property of an individual that accounts for his or her placement along this trait dimension' (McCrae and Costa 1996, p. 235). 'Agreeableness,' for example, refers simultaneously to a person's tendency to exhibit the behaviors one calls 'agreeable' and to an internal structure that corresponds to, and purportedly explains, this overt tendency.

This theoretical position has an interesting implication for assessment. It dissolves the distinction between the assessment of overt tendencies and internal psychological systems (Sect. 2.1, above). Five-factor theorists assess an individual's average behavioral tendency and interpret the measure as an index of both what the person does (an overt behavioral disposition) and what the person has (an internal psychological structure).

Although the simplicity of this approach may be appealing, its underlying logic can be questioned. Two concerns are of particular note. First, the five factors are identified in analyses of populations, yet are assumed to exist in the psychological make-up of each and every individual in the population (McCrae and Costa 1996). On purely statistical grounds, there is no reason to expect that group-level statistical parameters will replicate themselves at the level of each member of the group. (As a simple example, a group may average 40 years of age, yet no one in the group may be 40 years old.) Second, five-factor theory explains overt dispositional tendencies (e.g., a person's consistently agreeable acts) by inferring hypothetical causal constructs that contain the very properties that one is supposed to explain (e.g., agreeableness). This approach violates a standard principle of scientific explanation. As Hanson (1961, pp. 120–1) explained, 'What requires explanation cannot itself figure in the explanation,' for example, 'if the colors of objects are to be explained by atoms, then atoms cannot be colored' (also see Nozick 1981). This principle of explanation suggests that one should not explain dispositional tendencies by inferring psychological

constructs that directly embody those tendencies. It follows, then, that the assessment of surface-level tendencies and of internal psychological systems that explain those tendencies should be construed as separate tasks (Cervone et al. 2001).

3.2 Assessing Cognitive and Affective Systems and Persons-in-context: Social-cognitive Theory

An approach to personality and assessment that differs markedly from five-factor theory is that of social-cognitive theory (reviewed in Cervone and Shoda 1999). Social-cognitive theory rests on three main principles. Persons and sociocultural environments are viewed as reciprocally interacting systems. The core person variables are cognitive and affective mechanisms through which people interpret the world, reflect upon themselves, and self-regulate their behavior. Finally, personality is viewed as a complex, dynamic system; social-cognitive and affective mechanisms function in concert as interacting systems that underlie the coherence of personality functioning (Cervone and Shoda 1999).

This theoretical perspective has significant implications for assessment. One implication is that assessments of surface-level behavioral tendencies and of underlying psychological systems must be kept distinct. If overt tendencies reflect complex interactions among multiple underlying social-cognitive mechanisms, then there may be no simple relation between an overt behavioral pattern and any individual social-cognitive variable. The assessment of overt tendencies then cannot substitute for the assessment of internal structures. A second implication is that personality assessment must be contextualized. People's self-regulatory abilities enable them to vary their behavior strategically in accord with the perceived opportunities and demands of environmental settings. One must attend to these contextual variations to appreciate fully the distinctive features of an individual's personality (Mischel and Shoda 1995). A third implication is that personality assessment should include more than just an assessment of current dispositional tendencies. People possess potentials that may not be reflected in their typical daily activities. A person may, for example, possess a potential for leadership or for parenthood that only manifests itself when relevant circumstances arise (Caprara and Cervone 2000). Social-cognitive assessors commonly target skills and belief systems through which individuals contribute to their own development over the course of time (Bandura 1986). Finally, social-cognitive theory and research indicates that the content of personal beliefs, and the interconnections among elements of personal and social knowledge, may vary idiosyncratically from one person to another (Cantor and Kihlstrom 1987). This implies that assessments must be highly sensitive to individual idiosyncrasy. Social-

cognitive investigators commonly assess personal belief systems through idiographic methods (Cervone et al. 2001).

4. General Comments

The divergent conceptions of personality assessment that derive from five-factor theory as compared to social-cognitive theory underscore the more general point made earlier. To assess personality, one must rely upon a theory of personality. Questions of personality assessment and personality theory are inevitably intertwined.

In recent years, basic research on biological, affective, and cognitive processes increasingly has informed the study of molar behavioral patterns and differences among individuals. These advances have begun to yield an integrative psychology of personality in which diverse sources of knowledge are brought to bear upon questions of personality functioning and individual differences (Caprara and Cervone 2000). An ongoing challenge for personality assessors, then, is further to develop assessment techniques that do not merely describe surface-level behavioral patterns, but also shed light on specific underlying psychological processes that contribute to the consistency and coherence of personality.

Personality Development and Temperament

Personality refers to the profiles of stable beliefs, moods, and behaviors that differentiate among individuals in a particular society. The exact form of expression and the number of profiles will vary with culture, as the number and variety of animal species vary with the ecological setting. New England Puritans would have regarded variation in piety as a major psychological trait, and citizens in Confucian China would have treated loyalty to the father as a central personality characteristic. Neither piety nor filial loyalty are regarded as primary personality traits by contemporary psychologists.

The personality types believed to be most prevalent in contemporary industrialized societies refer to usual styles of social interaction; degree of adherence to the ethical standards of the community; vulnerability to the emotions of anxiety, guilt, and anger; and receptivity to new ideas, beliefs, and attitudes. However, among individuals living in ancient agricultural societies, composed of small, stable geographically separate villages, variation in sociability would be less critical for adaptation than this trait is in the large cities of contemporary, industrialized nations.

The term temperament, on the other hand, refers to the profiles of mood, behavior, and physiology, believed to be under some genetic control, that appear relatively early in life and, together with experience, become the major personality traits of individuals in a particular society (Bates 1987). Temperamental qualities in children believed to be important at the start of the twenty-first century refer to ease of arousal to stimulation; the form and efficiency with which that arousal is regulated; activity level; irritability; form of reaction to unfamiliar people, objects, and situations; and capacity for sustained attention.

Scholars who believe that temperamental categories are applicable to adults have nominated avoidance of danger, seeking of novelty, dependence on social rewards, emotionality, activity, and sociability as primary temperamental characteristics (Buss and Plomin 1984).

1. Temperamental Contributions to Personality

The assumption that a young child's temperament makes a contribution to the older individual's personality has a long history. Hippocrates and Galen, two physicians living in ancient societies who were the founders of the temperamental theory, believed that the relative concentrations of four body humors—blood, phlegm, and yellow and black bile—created within each person a combination of the opposed dimensional qualities of warm versus cool and dry versus moist. The four temperamental types, called melancholic, sanguine, choleric, and phlegmatic, were the products of a particular combination of these two dimensions which were influenced, in part, by local climate and the person's diet. Melancholics were high on the qualities of cool and dry because they possessed an excess of black bile and that is why they were tense, anxious, and depressed. Sanguine individuals were high on the warm and moist qualities because of an excess of blood and were outgoing and optimistic. The choleric was high on the qualities warm and dry because of an excess of yellow bile, and, as a result, was easily angered. The phlegmatic was high on the qualities of cool and moist because of an excess of phlegm and was low in energy and initiative. These concepts remained popular among Europeans and Americans until the end of the nineteenth century.

Interest in the contributions of temperament to

personality receded during the first half of the twentieth century when political forces led to a rejection of the idea that biological processes contributed to personality. However, the contribution of temperament returned when the psychiatrists Alexander Thomas and Stella Chess (1977) nominated nine primary temperamental dimensions in children, along with three synthetic types that they called difficult child, easy child, and the child who is slow to warm up to unfamiliar situations. The difficult child, which was the least frequent category and comprised about 10 percent of the study group, was rather more likely than the other two to develop psychiatric symptoms in later childhood.

2. Reactivity to Stimulation in Infants

Ease of behavioral and physiological arousal to varied forms of stimulation, and the form of regulation of that arousal, are primary temperamental qualities in infants and young children (Rothbart 1989, Kagan 1994). Some infants become easily aroused by sight, sounds, and smells and thrash, cry, babble, or smile at these events. Other infants show minimal signs of arousal to the same stimulation. It is believed that about 20 percent of healthy, four-month-old infants react to varied forms of stimulation with frequent distress and vigorous motor activity. One-fourth of these infants, who are called high reactive, become very subdued, shy, fearful children in the second and third years and are more likely than others to develop anxious symptoms by school age. By contrast, about 40 percent of healthy infants show the opposite profile of a relaxed and minimally distressed reaction to stimulation. About one-fourth of these infants, who are called low reactive, become sociable, bold, and affectively spontaneous preschool children and minimally anxious seven year olds (Kagan 1994). A temperamental vulnerability to anxiety helps to explain why only a minority of children react to a particular stressful event with an anxious symptom, whether the traumatic event is an earthquake, kidnapping, divorce, or abuse. Only a fairly small proportion of children, usually less than 40 percent, react to the traumatic event with a fearful symptom or chronic anxiety.

Social experiences, especially experiences in the family and with peers, determine whether high reactive infants will develop a fearful personality and whether low reactive infants become bold extraverts. Hence, only about 15 percent of children who are extremely shy and anxious in the preschool years become introverted adolescents or adults (Caspi et al. 1988), and both the anxious-shy and the bold-sociable types are under modest genetic control.

There is disagreement as to whether temperament should be viewed as a continuous dimension or as a qualitative category. For example, some regard the

tendency to approach or to withdraw from unfamiliar people and situations as a continuous dimension, while others believe that the child who usually approaches unfamiliar people and events and the child who usually avoids these events belong to separate, discrete categories. Because only about 15 percent of young children are consistently shy, avoidant, and timid in a large number of unfamiliar situations, while most children are subdued in only one type of situation, it is likely that the former child belongs to a qualitatively discrete group.

Most scientists believe that each of the many temperamental types possesses a unique set of inherited physiological features. Although most of these biological features are not yet discovered, it is known that fearful-avoidant children show greater cortical activation of the right frontal, compared with the left frontal, area as measured by absence of alpha activity in the EEG on the right side (Davidson 1994, Fox et al. 1994).

The brain contains over 150 different chemical substances, each of which influences the excitability of particular ensembles of neurons and brain circuits. It is assumed that children inherit different concentrations of these molecules, as well as different densities of the relevant receptors present on neuronal surfaces. As a result children are disposed to different mood and behavioral reactions. One example involves an enzyme called dopamine beta-hydroxylase. This enzyme, which is under genetic control, is required for the final step of the synthesis of norepinephrine. Children who have low levels of this enzyme will necessarily have less norepinephrine in their brain. Because brain norepinephrine renders a child vigilant and may increase the probability of a state of fear to novelty, children with low levels of the enzyme would be expected to be less fearful. Boys who are very aggressive or antisocial, often called conduct disorder, seem to be unafraid of punishment. These children have low levels of this enzyme (Rogeness et al. 1988). Dopamine, another essential brain neurotransmitter, affects motor behavior and cognitive processes mediated by the frontal cortex. Because the frontal cortex mediates planning and control of impulsivity, it is possible that children who inherit low levels of dopamine in the frontal area will be unusually impulsive. The rationale for administering the drug Ritalin to children who have been diagnosed as impulsive or hyperactive is that this drug increases the level of dopamine in the frontal cortex and, therefore, helps children control impulsive and potentially inappropriate behavior.

3. The Role of Environment

Children are exposed to different environments over the course of childhood and these environments influence temperament in different ways. Therefore, there will be a large number of different personality

profiles emerging from the combination of early inherited temperament and experience. Some of the important experiences include the socialization practices of the parents, the relationship to brothers and sisters, success or failure in school, and the quality of relationships with peers. The social class of the child's family always exerts continuous influence on the personality that develops. A large birth cohort of children born on the island of Kauai followed from birth to the fourth decade of life revealed that the social class of the child's family and early temperament were the two most important influences on the adult personality. Minimally irritable infants who were born to highly educated families were least likely to encounter school failure, display delinquent behavior, or to develop symptoms requiring referral to a physician or psychologist (Werner 1993).

3.1 Types of Challenges

The most frequent personality profiles that develop in a particular culture are a function of the challenges to which the children in that culture must accommodate. Children in most settings deal with three classes of challenge: (a) unfamiliarity, especially unfamiliar people, tasks, and situations; (b) requests by legitimate authority for conformity to and acceptance of their standards, especially standards for competent task performance; and (c) domination by and/or attack from peers. In addition, all children must learn to control two families of emotions: anxiety, fear and guilt, on the one hand, and, on the other, anger, jealousy, and resentment.

4. Temperament and Moral Emotions

Variation in the intensity of the moral emotions of shame, guilt, and anxiety can be influenced by the child's temperament and family experience. Shy, fearful children raised by mothers who used reasoning to socialize the child showed clearer signs of a strict conscience than most other children (Kochanska 1993). Sensory information from the body ascends in the spinal column and projects to the ventromedial surface of the prefrontal lobe. Children who experience consciously more intense bodily stimulation might be more vulnerable to the moral emotions than those who experience less stimulation. School-age boys who were low reactive infants and fearless children often have low sympathetic tone in the cardiovascular system. Boys who are members of this temperamental group growing up in homes with nurturant parents who socialize achievement and the control of aggression are likely to become popular group leaders. The same type of child raised by parents who did not socialize asocial behavior and who played with peers who committed asocial acts are at slightly higher risk for becoming delinquents (Caspi et al.

1995). It is believed that a small number of criminals who commit violent crimes (probably fewer than 5 percent of all criminals) were born with a special temperament characterized by impulsivity and difficulty in controlling behavior.

5. Ethnicity and Temperament

Temperamental variation among ethnic groups is a delicate issue because of the ethnic strife that exists in many parts of the world. The average genetic distances for 100 different alleles monitoring physiological function measured in geographically separate populations were largest when Asians, Africans, and European-Caucasians were compared with each other. It is likely that some of these alleles make a modest contribution to variation in temperamental qualities. Asian-American infants, compared with European-Americans, are calmer, less labile, less vocal, and more easily consoled when distressed (Kagan et al. 1994). It is relevant that Asian-American adult patients with a psychiatric diagnosis require a lower dose of therapeutic drug than European-American patients (Lin et al. 1986).

6. Personal Control

The renewed interest in temperament has generated discussion over the degree of responsibility each person should have for his or her behavior. Western society has, in the past, been Puritan in its commitment to the belief that all individuals have sufficient will power to control their behavior in most situations. This view has been eroded since the 1950s as more citizens have become willing to excuse some asocial actions as due to temperamental factors that were not within the agent's sphere of control. It is not obvious that this permissiveness is more adaptive for a society than the traditional assumption that one of the significant products of human evolution is the capacity to monitor one's behavior.

J. S. Kagan

Personality Development in Adulthood

The study of personality is arguably the broadest subdiscipline in psychology in that it aims to understand how the whole person functions in the world (see *Personality Psychology*). Historically, personality psychology has concerned itself with grand theories about human behavior, questions about character, identity, and morality. Most of the empirical research on personality published over the past two decades fails to consider potential development in adulthood, reflecting, in part, an assumption that personality changes little in adulthood. Nevertheless there has been a long-standing interest in whether—and, if so, how—people change in systematic ways in the later years of life. The following sections summarize the research traditions and some of the central findings generated in the field of adult personality development.

1. Defining Personality Development

In part because personality draws so broadly from so many areas of psychology, including cognition, emotion, psychopathology, and motivation, consensus in the field over basic definitions is difficult to obtain (see *Personality Theories*). Even the preferred units of study (e.g., traits, behaviors, or psychological processes)

continue to be debated. Most recently, questions are being raised about the degree to which personality is bounded within the individual or is better represented in transactions between individuals and broader collective units. Importantly, different conceptual approaches to the study of personality lead to different predictions about and evidence for personality change in adulthood. Whereas personality development is considered by some to unfold naturally and unidirectionally from temperaments inherited at birth, other personality psychologists emphasize the need to consider a complex interplay of factors that contribute to personality development, including temperamental inheritance but more importantly exposure to different types of environments, acquired beliefs and expectations and the capacity for self-regulation (Bandura 1989).

In part, evidence for stability or change in personality in adulthood reflects which facet of human functioning is studied. To be clear, there is no dispute that people change in adulthood. They do. Adults are inevitably changed in idiosyncratic ways by the life experiences they encounter, including major life events, such as becoming a parent, or less dramatic but persistent experiences associated with, for example, the pursuit of a particular career and the consequent development of a particular type of expertise. However, change in adulthood is not automatically considered *personality development*. Rather, changes must be enduring, systematic (i.e., nonrandom), and predictable by age or life stage.

2. Major Approaches to Adult Personality Development

Conceptions of adult personality development have evolved out of two very different traditions in psychology; clinical psychology and life-span developmental psychology. The approaches and the findings about systematic change in adulthood reflect these different paradigmatic approaches to the study of lives. Due to considerable overlap between studies of individual differences and clinical psychology, many of the oldest and most influential theories of personality, most notably psychoanalytic psychology but also ego psychology and interpersonal psychology, were developed based on clinical observations of patients. Although strikingly different in its basic tenets, social cognitive theory of personality also evolved out of close connections between clinical and personality psychology, essentially addressing differences between normal and abnormal processing involved in basic psychological functioning. Thus, the oldest approaches to personality were tied closely to understanding psychopathology.

In contrast to the traditional individual difference approach, life-span psychology was born only in about

the 1970s and reflects the view that human development is a continuous adaptive process (Baltes and Goulet 1970). Life-span psychology aims to identify and illuminate normal developmental changes in all areas of psychological functioning, including but not limited to personality, from birth until death. Perhaps most notably, life-span psychology is distinguished by the presumption that human growth is at no time during the life course complete. Consequently, the different presumptions inherent in the two approaches direct attention to different research foci. Whereas traditional adult personality psychologists ask whether traits acquired in childhood persist across adulthood, whether particular personality crises present themselves at particular stages of life, or how personality disorders are transformed in later life, life-span psychologists are more likely to target specific age-related issues, like whether people grow wiser with age, whether conceptions of the self grow more or less complex over time, and whether self-regulatory processes change in systematic ways over time. As noted above, whether one finds evidence for stability or change depends importantly on where one looks and the particular questions one poses.

The next sections include a birdseye view of the earliest approaches to personality development and brief synopses of research on personality development deriving from the trait approach to personality development and from life-span developmental psychology.

3. Early Stage Approaches to Adult Personality Development

Following the tradition established by child developmentalists, early thinking about adult personality development was rooted in stage theories. Whereas Freud's (see *Freud, Sigmund (1856–1939)*) psychosexual stage model of personality suggested that personality was formed in early childhood and that, barring long-term psychotherapy, was highly resistant to change, his skeptical follower, Carl Jung (see *Jung, Carl Gustav (1875–1961)*), argued that the most interesting aspects of personality do not develop fully until middle age. Jung believed that only after basic biological and reproductive issues are resolved in early adulthood, are people freed to engage in more psychic pursuits. Jung posited that whereas in early adulthood biological imperatives predominate and demand adherence to gender roles, in mid-life feminine and masculine sides of people grow more integrated and spiritual concerns grow more salient. As people age, feelings and intuitions come to dominate thoughts and sensations. Thus, albeit in rather unspecified ways, Jung advanced the position that people developed in adulthood and that spirituality played an increasingly central role. Jung wrote far less about advanced old

age, but suggested that people predictably turned inward and deteriorated psychologically as they approached the end of life and wrestled with fears about death.

In the 1930s and 1940s, in Europe and the US, several stage theories, such as that offered by Charlotte Bühler, concretized thinking about adult personality development and allowed for empirical tests of theoretical predictions. Of these, Erik Erikson's (see *Erikson, Erik Homburger (1902–94)*) stage theory had the most enduring influence. Like Freud and Jung, Erikson was a classic ego psychologist and his theory was grounded in the psychoanalytic tradition. However, rather than focus on psychosexual needs, Erikson argued that human needs for psychological intimacy fueled systematic development that continued into old age. According to this epigenetic theory, people pass through a fixed sequence of stages during life each of which requires the successful resolution of a central psychic crisis. In early adulthood, the central issue involves the establishment of intimacy. In middle age, generativity, namely the passing on of power and knowledge to younger generations, is achieved or failed. In old age ego-integrity vs. despair (self-acceptance of a life lived or regret and dismay) is the focal crisis in life.

In the 1960s and 1970s, major research projects aimed at profiling adult development were undertaken at Yale (Levinson 1978) and Harvard (Vaillant 1977), which continued the stage theory tradition in the US and longitudinal studies undertaken in the 1930s began to come of age. As research participants in the Stanford Terman study of 'gifted' children, for example, entered adulthood, researchers began to examine connections between childhood and adult personality. The Child Guidance and Oakland Growth Studies undertaken at the University of California at Berkeley offered resources by which to examine predictable change. At the University of Chicago, a group of social scientists, including Bernice Neugarten, Morton Lieberman, and David Guttman, formalized the study of life-span personality development.

In the end, however, empirical support for stage theories failed to withstand empirical tests. Although interesting patterns were displayed in some very homogenous samples, identified developmental patterns failed to generalize broadly. Critics of stage theories claimed that the patterns that did emerge reflected the influence of consistent surrounding social structures around highly selected groups of people, not human development. Virtually all of the longitudinal studies included predominately (if not exclusively) white, middle-class individuals, often only males. In the 1980s, Costa and McCrae (1990) essentially waged a war against stage theories declaring that personality does not change systematically in adulthood. In a decade dominated by the *trait* approach to personality, the central and reliable finding

of the 1980s was that personality changes little after the age of 30 years.

4. *The Trait Approach to Adult Personality Development*

Traits are continuous variables represented by broadly encompassing lexical terms that account for individual differences (John 1990). Traits—such as shy, lively, outgoing, anxious, and intelligent—are conceptualized as predispositions within individuals to behave in certain ways manifest across a wide variety of situations. Gordon Allport (see *Allport, Gordon W (1897–1967)*) argued that cardinal traits are those around which a person organizes life (self-sacrifice). Central traits (e.g., honesty) represent major features and secondary traits are specific traits that help to predict behavior more than underlying personality (e.g., dress type, food preferences). Allport's definition is compatible with modern trait and temperament approaches to personality which attempt to describe people in terms of one or more central features of the person.

Personality psychologists in the trait tradition seek to identify the traits along which people differ and to explore the degree to which these traits predict behavior. Many taxonomies of traits have been offered over the years, but unquestionably the five-factor model is most widely accepted today (see also *Personality Structure*). Based on factor analysis of self-descriptions, the five traits that emerge reliably across many studies of Europeans and Americans are: (a) openness to experience, (b) conscientiousness, (c) extraversion, (d) agreeableness, and (e) neuroticism.

Traits and temperaments appear to be relatively stable through the second half of life (Costa and McCrae 1990). It appears that beyond the age of 30, extraverts remain extraverts and neurotics remain neurotics. Trait theorists have found reliable evidence for stability in personality well into old age. This finding emerges whether researchers ask individuals to describe themselves repeatedly over time or, alternatively, ask significant others, like spouses, to describe those same individuals repeatedly (Costa and McCrae 1990). It should be noted that even though persistent rank-order differences remain the same, there is some recent evidence that modest mean level changes may appear, with older adults scoring slightly higher than younger adults on agreeableness and conscientiousness and slightly lower on neuroticism, extraversion, and openness to experience (McCrae et al. 1999). Importantly, similar findings come from studies sampling Asian and European populations. However, identified changes are quite small. Overall, there is remarkable consistency in the characteristics that distinguish individuals from one another over time. There is some evidence that the core set of traits that differentiate people are genetically based and exert

their influence throughout the life course (Gatz 1992). Genetic influence is as strong in old age as early adulthood.

In summary, researchers adopting a trait approach to personality development find that along at least some of the important dimensions of personality, there is little change in personality well into old age. Critics of a trait approach, however, argue that traits communicate little about how people manage their lives in day-to-day life and because of the broadband focus exaggerate the consistency of behavior across time and situations. They criticize the trait approach for failing to better predict behavior and redirect focus to specific strategies (e.g., how an individual cognitively appraises a situation; expectancies, subjective values, self-regulatory systems, and competencies). Life-span approaches—influenced strongly by the social cognitive theory of personality (Bandura 1989)—view individuals as agentic creatures who shape their own environments (see also *Interactionism and Personality; Self-regulation in Adulthood*).

5. *Life-span Approaches to Adult Personality Development*

Rather than focus on taxonomies of personality, life-span developmental psychologists view development as a dynamic process aimed at adaptation (Baltes 1987). Two principal stays of life-span theory speak directly to personality. The first states that adaption is always time and space bound. In other words, behavioral adjustment must occur within a particular environmental and social niche. In life cycle context, what is adaptive in infancy and early childhood may not be adaptive in adolescence. Stranger anxiety, for example, may serve a highly adaptive function in infancy because it motivates dependent creatures to stay in close proximity to caregivers. It may also facilitate attachment to primary adult figures, a key developmental task of early life. Yet, stranger anxiety among adults is clearly maladaptive. Similarly, it can be argued that pursuing multiple prospective mates is adaptive in adolescence and early adulthood as people 'practice' intimate relationships but less so in middle and old age at which point emotional investment in a select few may hold greater gains than the continual exploration of all possible mates.

The second stay of life-span theory is that development inevitably demands selection (Baltes and Baltes 1990). In order for specialized (i.e., effective) adaptation to occur within a particular social, historical and physical niche, active and passive selections must be made. As people age, they come to have greater choice in the selection of environments and select environments that support their self-views. Throughout adulthood, people actively construct skills and hone environments to meet selected goals. There is good evidence that people narrow their social

spheres with age, for example, forming increasingly well contoured social convoys that accompany them throughout life (Carstensen et al. 1999). Caspi and Herbener (1990) found that people tend to choose spouses similar to themselves, and further show that people who have spouses similar to themselves are less likely than people with dissimilar spouses to display personality change in adulthood. Thus, it may be that stability is maintained across the life course because people actively create environments that maintain stability.

Finally, life-span theory holds that development is never fully adaptive because adaptation to one set of circumstances inevitably reduces flexibility to adapt to another. In this way development always entails gains and losses. Subsequently, life-span theory obviates the presumption that antecedent losses are the only or even the primary reasons for changes that occur with age and examines how people's relative strengths and weaknesses at different points in the life cycle influence successful adaptation.

5.1 Personality Development from a Motivational Perspective

Life-span developmental approaches, because they are rooted in adaptation, lead naturally to consideration of the ways that goals and goal attainment may change throughout the life course (Baltes and Baltes 1990, Brandtstädter et al. 1999, Carstensen et al. 1999) (see also *Adulthood: Developmental Tasks and Critical Life Events*). Motivational psychologists presume that there is continuity in basic human needs for competence, relatedness and autonomy across the life course. There is every reason to expect, for example, that regardless of age, people seek to control their worlds (see also *Control Behavior: Psychological Perspectives*).

Researchers who take a goal-focused approach have brought a different set of findings to bear on discussions of personality and aging, showing that goals and preferences do change with age and influence behavior. Carstensen and co-workers, for example, have shown that the perception of time left in life importantly influences social goals. Because aging is inextricably and positively associated with limitations on future time, older people and younger people differ in the goals they pursue (Carstensen et al. 1999). Older people are more likely to pursue emotionally meaningful goals whereas younger people are more likely to pursue goals that expand their horizons or generate new social contacts. Brandtstädter et al. (1999) argue that people adjust goal strivings to accommodate external and internal constraints placed on goal achievement at different points in the life cycle; a central finding coming out of this line of work, for example, is that older people respond to the loss of resources in advanced age by downgrading the importance of some previously desirable goals.

5.2 Emotion and Personality

Another way of conceptualizing personality, which is particularly conducive to life-span approaches, places emotional experience and emotional regulation at the core. In this view, emotions are not related simply to personality, they are the essence of personality (Carstensen et al. in press, Rothbart and Derryberry 1981) (see also *Adulthood: Emotional Development*). The emotions people feel when they face challenges, and the effectiveness with which they learn to regulate their emotions, are the cardinal components of personality development, forming the basis of individual differences in persistent tendencies to behave, think and feel in day-to-day life. Individual differences in the propensity to experience specific emotions influence not only the psychological and biological reactivity of the person in the moment, but come to influence conscious choices about preferred environments, behavioral styles, and also determine the social partners to which people are drawn.

Ryff (1995) has taken a differentiated approach to understanding emotions and well-being across the life-span. Rather than calculating global positive and negative affect as indicators of psychological well-being, Ryff conceptualizes well-being in terms of self-acceptance, environmental mastery, purpose in life, personal growth, positives relations with others, and autonomy. The dimensions appear to have differential relationships with age, with older adults scoring higher than younger adults on Environmental Mastery and Autonomy, but lower on Purpose in Life and Personal Growth. There also appear to be life-span developmental trajectories concerning the relationship between people's conception of their present status and their ideal selves along these dimensions. Older people tend to have less distance between their actual and ideal selves than do younger adults.

An emotion approach to personality has particularly intriguing implications for adult development because in adulthood emotions appear to grow more complex (Carstensen et al. in press) and emotion regulation appears to improve (Gross et al. 1997). With advancing age, the emotion-cognition-personality system also appears to become more-differentiated, with emotions becoming linked to an ever-increasing array of cognitions. To the extent that such changes influence motivation (e.g., Izard and Ackerman 1998), modify thinking and reasoning (Labouvie-Vief et al. 1989), or result in qualitative changes in subjective well-being (Ryff 1995), personality is importantly influenced.

5.3 Wisdom and Resilience

As noted above, the focus on adaptive development inherent in life-span approaches generates questions about the ways in which aging people adjust to changing resources and changing contexts. There is a

delicate balance between gains and losses that occurs in the second half of life that have important implications for personality. As people enter advanced ages, nearly inevitably they encounter increasingly difficult challenges, including the deaths of friends and loved ones, assaults on physical health, and threats to social status (see also *Coping across the Lifespan*). At the same time as experience in life increases, perspectives change. In some ironic way, the familiarity of losses may even make losses easier to take. Considerable focus in lifespan psychology, thus, has been on the ways that people effectively adjust in later adulthood. Resilience (Staudinger et al. 1995) and wisdom (Staudinger 1999) have been particular targets of interest because they involve the use of age-based experience to compensate for losses in circumscribed domains. Studies of wisdom, for example, show that contrary to popular lore, wisdom is unrelated to age in adulthood (Staudinger 1999). Even though experience-based knowledge does increase with age, wisdom requires a complex array of abilities that draw on multiple functions, some of which decline. Under optimal conditions, old age may be the time in life for wisdom to best emerge, but it does not do so normatively.

6. Integration of Approaches and Findings about Adult Personality Development

Does continuity or change in personality best characterize adulthood? The answer is a qualified 'yes' to both continuity and change. Along some basic descriptive dimensions, such as openness to experience and extraversion, people remain remarkably consistent in adulthood. However, in other domains just as central to personality, such as motivation and adaption, there is evidence for systematic change across adulthood. Goals change predictably with age, emotion regulation appears to improve, and well-being takes on different qualities.

7. Future Directions

The fundamental challenge that confronted personality researchers a century ago remains largely the same today: predicting and understanding individual differences in behavior. Students of adult personality development face the additional challenge of understanding how the differences that distinguish one person from another may change systematically over time. Although considerable progress has been made, the bulk of empirical findings generated simply show that prevalent assumptions about adult personality development in the twentieth century were wrong. For example, people do not appear to pass normatively through a fixed series of stages; and along broadband

dimensions characterized as basic traits, people change very little in the second half of life. Approaches that focus on motivation and emotion are newer, but initial findings suggest that they may shed considerable light on ways that individuals change in middle and old age. Finally, at the time of this writing, the human genome project very recently was declared complete. Few, if any, scientists expect that genetic findings alone will shed much light on personality. However, they may well help to do away with customary language and algorithms (such as 'heritability coefficients') that have given credence tacitly to the idea that environmental and biological influences can be cleanly separated. Whereas in past decades, substantial discussion has centered around whether biology or environment was most influential in personality development, personality researchers will now begin to address the more interesting and more important puzzle which lies in the interaction between the two.

Personality Development in Childhood

To understand personality development in childhood, we first define personality, and how it is structured. Then we discuss how the definition is typically translated into research, noting some curious omissions and quirks in the literature. Next, we consider the raw materials of personality and how they are changed over time. Once this is completed, we discuss outcomes of research on personality development in children.

1. Personality Development as the Organization of Individual Differences

First, perhaps the most basic question is what is personality? Common personality characteristics can be shared by groups of people—say, women, Russians, three-year-old boys—but usually we think of personality in terms of defining aspects of individual persons. In modern theory, personality is concerned with the organization of each person's unique configuration of individual differences. When personality is defined this way, rather than one difference at a time (e.g., introversion), it is possible to recognize that over time conflict within a person may occur due to competing and sometimes incompatible needs (see *Personality Structure*). The self-organization of the diverse elements that live under a common skin is motivated by the need to resolve intrapersonal conflicts and to adapt, or adjust, to the world beyond the individual. For example, we would expect an intelligent, introverted child to make compromises in the service of social adjustment different from those made by a similar child who is intelligent and extraverted. Personality is concerned with the accommodations and compromises each individual must make among the competing demands of these differences. The adjustment processes occur over time, and involve genetics, maturation, and learning. In this light, personality development in childhood can be seen as one segment in a life-long process that leads to the formation of a stable adult personality structure (see *Personality Development in Adulthood*). Common but untested assumptions are that processes of personality development are more dynamic in childhood than in adulthood, and that personality structure is more fluid and open to change in the former than in the latter. Personality development does not necessarily stop after childhood, but that period is regarded as a time of special sensitivity for the formation of the broad structure.

Second, we need to recognize how the definition of personality is typically translated into research. There are historical traditions and precedents in the personality development literature that influence the way professionals engage in research in the area. For example, the personality literature does not usually regard individual differences in ability in general, and intelligence in particular, as part of its domain, despite the illustration given in the preceding paragraph and the obvious importance of intelligence to adaptation. Similarly, differences in attachment are not well integrated into the rest of the personality development literature, despite the importance of attachment processes for adaptation. For another (but related) example, readers will sometimes encounter a distinction between 'personality development' and 'emotional development.' Some early writers used the term emotional development to focus on attachment and the psychodynamic approach to personality devel-

opment, and to separate it from other kinds of personality development. Detailed historical analyses make some of these oddities understandable, but such analyses are beyond the scope of this review (see *Infancy and Childhood: Emotional Development*). The point here is that definitions must be translated into measures and procedures, and historical precedents can lead to potential biases in the translation.

Third, developmental processes for each individual occur within a specific historical time, kinship system, social learning environment, and cultural context. Some aspects of personality are tied directly to such contextual factors (e.g., parental divorce), and leave residues. These life experience-based residues represent a legitimate aspect of personality. In the past, residues of experience relevant to personality have been conceptualized mainly in terms of 'learning,' or 'socialization' (see *Social Learning, Cognition, and Personality Development*). More recently, another approach has emerged. Residues of experience relevant to personality can be conceptualized in cognitive and information-processing terms. For example, cultures differ in the ways they teach children skills. In some cultures, mixed-age peer groups engage in competitions, with older peers teaching younger children. In those cultures, substantive knowledge acquired during peer interactions in certain domains is fused to specific beliefs about peer relations and social interaction that is missing in other cultures.

Fourth, given the potentially powerful influence of social learning and sociohistorical contexts, it is a major challenge for personality development theory to identify panhuman substantive dispositions. That is, in the past the majority of researchers have assumed that (a) personality development in all human children can be characterized by individual differences in a small set of enduring characteristics; and that (b) these characteristics induce the children to respond in consistent ways over time and across settings. These two assumptions may not be justified, and at the least they need to be evaluated empirically. Phrased more positively, personality development theory needs to integrate findings of cultural diversity and variation in children's personality with the assumptions about the nature and assumed roles for panhuman dispositions. To accomplish this task, researchers must select a small number of dispositions and enduring characteristics from the vast array of human differences that will prove to be important for theory or for life outcomes. Ideally, the ones chosen for attention in childhood will be broad in scope, related to competence in adulthood, and likely to become part of later personality structure. On an *a priori* basis, we might expect all cultures to be concerned with the development characteristics associated with success in the two major domains of 'love' (sex roles, reproduction, kin relations) and 'work' (reliability, rule compliance). It is possible, of course, that each culture will encourage the development of somewhat different configurations of characteristics

within these two major domains, based on the ecological and social structures within which they live (see *Gender Differences in Personality and Social Behavior*).

2. Four Perspectives on the Substance of Personality and Development

To investigate the substantive nature of personality development, some further 'simplifying' assumptions are required. There have been four major perspectives on the identification of substantive characteristics in personality development (see Caspi 1998). The first major perspective is the most direct approach to childhood personality because it accepts it as a biological 'given.' It involves temperament, and focuses on childhood and infancy. Temperament, an important concept in developmental psychology, refers to early appearing, stable individual differences derived from the constitutional or biologically determined makeup of individuals (see *Temperament and Human Development*). It represents the presumed biological, emotional core around which later personality coalesces. For example, children show important individual differences in fearfulness or motor activity, and these may have heritable components. These are the kinds of differences that warrant attention developmentally because in theory they could constrain ontogenetic processes, and the kinds of experiences individuals accumulate as they move through life. Thomas and Chess (1977) stimulated modern interest in childhood temperament when they identified nine categories of differences based on clinical experiences with very young children. Examples are 'activity level' and 'persistence.' Second-order constructs were proposed to reduce the nine dimensions to three ('easy,' 'difficult,' and 'slow to warm up') based on factor analyses. Subsequent research showed that the original nine dimensions could not be recovered from item-level factor analyses. Instead, five to seven factors appeared. We will return to this perspective later.

Second is the social-cognitive process perspective of Mischel (1999). Researchers could identify individual differences in an enduring skill or tendency in children that could shape the ways children interact with their physical and social environments. These skills need not necessarily be conceptualized as traits (see *Personality and Social Behavior*). The cumulating effect of the skill on the child's outcomes could in theory have important long-range consequences (e.g., Kochanska et al. 1998). For example, the skills associated with delay of gratification are potentially relevant to both 'love' and 'work,' so they represent an especially good substantive characteristic to investigate as an aspect of personality development. Consistent with this perspective, Mischel et al., (1988) found that preschool children who are skilled in delay of gratification appear to interact systematically with the environment in

ways that allow them to achieve tasks more efficiently than their peers. Over time and settings, these skilled children accumulate accomplishments that allow them as adolescents to have higher social competencies and educational levels, and eventually as adults to achieve higher socioeconomic standing than other adults.

Third is the 'developmental targets' perspective (Caspi 1998), which is perhaps a meta-perspective because it can include both dimensional and typological theories under its umbrella. The goal here is to identify developmental antecedents of dispositions that are parts of stable adult personality structure. For example, extraversion and neuroticism are two major dimensions in adult personality structure, and represent developmental targets. It is important to know how these dimensions are formed developmentally. High levels of fearfulness or motor activity in childhood may be antecedents of adult neuroticism or extraversion, respectively. Once an empirical relation is demonstrated, then theoretical process mechanisms could be offered to explain how motor activity may be transformed or channeled into the targeted difference (e.g., extraversion). In effect, adult personality structure provides the target end states, and research is directed to finding its precursors. This approach requires knowledge of major, reliably appearing, and enduring adult personality structures (e.g., extraversion, neuroticism), but also empirically established antecedents that are not associated uniquely with configurations of sociohistorical events or cultural practices. (Of course, researchers (e.g., Elder 1999, McCrae et al. 1999) are interested in these socio-historical and cultural patterns as a special class of personality phenomena.) Until recently, there was no consensus on the nature of adult personality structure, much less antecedents, that could meet these criteria, so personality development based on developmental targets was inhibited.

The fourth perspective could be regarded as a specialized typological version of the case outlined in the preceding paragraph. It is the person-centered, categorical approach of Block (1971). Unlike the researchers who assume personality is structured in terms of continuous underlying dimensions, the typological approach assumes that persons are better characterized as belonging in discrete categories depending on the configuration of attributes. Based on extensive empirical data on personality descriptions of persons as they moved from early adolescence to adulthood, Block had trained clinical judges sort descriptions into piles (Q-sorts), using a continuum from least characteristic to most characteristic. This Q-sort technique is person centered because each attribute is compared with other attributes in the same person. Statistical analyses can then be used to identify clusters of persons with similar Q-sort configurations. At least three adult types were found, and can be described as (a) ego-resilients, who are well functioning in all major domains; (b) overcontrollers, who were

shy and lacked many interpersonal skills; and (c) undercontrollers, who were hostile, disagreeable, and showed little concern for others. These types could be regarded as developmental targets for developmental research. Longitudinal research with children (Hart et al. 1997) showed that three personality types could be replicated, suggesting avenues for theories of personality development. The largest category (ego-resilients) represents persons who are well adjusted; the other two smaller categories represent persons whose adjustment suffers from either overcontrol or undercontrol. At the least, such outcomes suggests that personality development should focus substantively on resilience and control. What is less clear is whether these types represent good developmental targets, in the sense of discrete natural classes, or are unique configurations of persons along some other underlying dimensions. It also is not clear whether these types represent the personality development of females as well as they do males (Caspi 1998).

3. Personality Development and the 'Big Five'

Let us move our discussion from perspectives to further research. In a series of pioneering papers in personality development, Digman and his colleagues in Hawaii began investigating the structure of child personality in teachers' ratings. Digman selected his variables to cast a wide net, and in some studies included assessments of intelligence, peer ratings, and various aptitude and personality batteries. He appeared to have no overriding theoretical agenda. At the time much of his data were collected, Digman (1994) suggested that he was an advocate for a model of child personality that included no less than ten factors. When his data were analyzed, however, a five-factor solution was reliably found (e.g., Digman and Inouye 1986). Digman recognized that the pattern he found in the child personality data was consistent with a similar pattern found in adults (e.g., Digman 1990). Perhaps the developmental targets approach could be useful after all. The time was ripe for a union between personality development researchers and researchers working with adult personality structure.

The number five seems to have a certain magical quality for personality researchers. The five-factor model, or the more descriptively accurate label 'Big Five' (BF) approach, currently occupies center stage in adult personality research (see *Personality Theories*). When people are given enough time and freedom to express their evaluations of others, five broad dimensions reappear reliably. These five dimensions are abstract 'supertraits' that summarize lower level patterns of individual differences. A useful mnemonic for remembering the dimensions of the BF is the acronym OCEAN: openness, conscientiousness, extraversion, agreeableness, and neuroticism. (The

memory aid does not convey the relative size or importance of these dimensions: extraversion and agreeableness are probably larger factors than the others.)

Two leading temperament researchers, Halverson and Kohnstamm recognized the need to bring child personality development researchers together with leading researchers working on the structure of adult personality, and they organized a conference. Papers presented at this meeting, and a few others, were published in a subsequent milestone volume entitled *The Developing Structure of Temperament and Personality from Infancy to Adulthood*. The chapters in Halverson et al. (1994) suggested possible links among temperament differences in infants and toddlers and later personality structure in children and adults. Contributors to the Halverson et al. (1994) volume showed how aspects of temperament might be linked to BF personality structure. For the personality development researchers, temperament was the focal concept because in developmental psychology, it refers to early-appearing, stable individual differences derived from the constitutional or biologically determined makeup of individuals.

Prior to the Halverson et al. (1994) syntheses, the temperament researchers and the BF researchers were like two separate, isolated tribes. Temperament research was conducted largely as a kind of developmental psychology. Temperament was conceptualized as biobehavioral individual differences in young children, and not as personality structure, *per se* (see *Personality Development and Temperament*). Because young children cannot provide verbal self-reports, temperament researchers were usually forced to rely on objective measures and ratings by expert observers. In contrast, BF research was conducted largely as personality psychology, conceptualized as the structure of individual differences in adults. Because adults can provide verbal self-reports, BF researchers rely much more on self-reports than on objective measures or expert ratings for their data. Some BF researchers seemed mildly interested in the temperamental antecedents of the structure, but others most emphatically were not (see Hofstee 1991, p. 185). Many of the contributors to the Halverson et al. (1994) volume were internationally recognized authorities on temperament, and their suggestions about links between early-appearing, emotional dispositions and later BF personality structure gave credibility to the general line of thought.

One idea reinforced at this conference was that some aspects of temperament provide the developmental substrates for later, major dimensions of personality. One route is to link temperamental characteristics in infants and young children to each of the major BF dimensions. In theory, temperamental differences in activity at infancy could be linked positively to extraversion, and negatively to conscientiousness (e.g., Caspi 1998). Another route is to

suggest ways that temperaments lay a functional foundation for later personality dimensions. For example, infants show temperament-related differences in reactions to frustration. Some infants become so upset when frustrated that they appear to be unable to respond adaptively to the frustrating event, whereas other infants seem to be modulate their emotional reactions and deploy attention in adaptive ways. Ahadi and Rothbart (1994) suggested that a kind of superordinate temperament called 'effortful control' (EC) might regulate reactions to frustration. Furthermore, processes underlying EC might lay a functional foundation for both conscientiousness and agreeableness. This provocative idea suggests that (a) temperament-based processes like EC are related to perceptual processes of attention; (b) seemingly different dimensions of adult personality may be related through their common functional connection to the control of frustration; and (c) two of the major dimensions in the BF may have a common developmental substrate, and may differentiate over time into functionally separate self-regulatory systems. The implications for the socialization of emotions, achievement, and social skills are great (e.g., Kochanska et al. 1998).

In 1998, Kohnstamm et al. delivered some hard evidence in *Parental Descriptions of Child Personality: Developmental Antecedents of the Big Five?* (Kohnstamm et al. 1998). They offered a seven-country study of parents' description of their children's personality. The seven countries involved were Belgium, China, Germany, Greece, The Netherlands, USA, and Poland. The book's title expresses the continuity beginning with early temperament research, on to Digman's pioneering work, through the Halverson et al. (1994) meeting of the minds, to the massive cross-cultural data set presented in this book. Rather than relying on top-down, theorist-imposed descriptors in existing temperament or personality measures, contributors to the Kohnstamm et al. volume asked parents to use their own words to characterize their children. The explicit assumption was that people in all seven countries frequently mention those characteristics that they think are most important or basic. In all seven countries, parents described children between the ages of two and 13 years. The descriptions were collected during face-to-face interviews by teams native to each country's language and culture. Using elaborate coding manuals, descriptions were categorized into units, which were inspired by the BF, with subcategories or facets derived mostly inductively. In addition, responses were coded as positive or negative. For example, in coding the extraversion descriptions, Kohnstamm et al. used 1A (sociability), 1B (dominance, leadership, assertiveness) and 1C (activity, pace, tempo). In this system the positive-negative poles are added so that 1A+ would include 'enthusiastic,' whereas 1A- would include 'tendency to shut self off.' After training, coders' agreement over the main categories was between 80 and 90 percent.

In theory, most cultures have a stake in supporting positive relations among people and controlling conflicts. It is reasonable then to expect persons in all cultures to recognize differences associated with harmonious relations, and to socialize children accordingly (see *Self-regulation in Childhood*). It is telling, perhaps, that the B5 dimensions that focus on interpersonal relations, extraversion and agreeableness, together account for approximately half of all parental descriptions of children. None of the other three dimensions rival either of the two interpersonal dimensions in terms of proportions of descriptions. Extraversion is one of the core concepts of trait psychology, and some form of it is measured in all widely used personality measures. In every country except Greece, extraversion was the single most frequently mentioned category at 28 percent of the descriptors (In Greece, agreeableness and extraversion were equal in importance.)

As a distinct aspect of personality, agreeableness is less well understood than extraversion. In part this may be due to an undifferentiated understanding of social behavior, which includes both social impact (extraversion) and motives to maintain positive relations with others (agreeableness). Eysenck (1994) emphasized the former aspect of social behavior in his trait model. As a consequence, personality researchers interested in the dispositional foundations of social behavior focused on extraversion at the expense of agreeableness. If agreeableness is related to 'love,' and to motives to maintain positive relations, then it is not difficult to see potential developmental continuities, particularly links to interpersonal conflict, and to childhood problems like difficult or disruptive behavior and antisocial tendencies. Data from the Kohnstamm et al. book show that in parental description, agreeableness is a large dimension, accounting for from 17 percent (China) to 26 percent (Greece) of all descriptions.

Because the Kohnstamm et al. work is massive, it is possible to give only a flavor of the findings for some of the other 'lesser' personality dimensions. Of the remaining dimensions, openness seems to be the largest category in free descriptions, but with major cultural differences. Data from the Kohnstamm et al. book show that parents in the USA make use of openness descriptors almost twice as often as do parents in all other countries except Germany. Further data focus on emotional stability (positive pole) and neuroticism (negative pole). Like extraversion, neuroticism is easily linked conceptually to early appearing temperaments (e.g., 'adaptability,' 'quality of mood'). Given the long history of research and theory on the dimension, and the applied importance of this dimension for mental health and child guidance clinics, many professional psychologists will be surprised to learn that across all seven countries, fewer than 10 percent of all parental descriptors fell into this category. One conclusion is that on a worldwide basis

most parents are not concerned about negative emotionality, anxiety, or self-confidence in their children. These qualities may be taken for granted, which is not the same as being unimportant.

Previously, we suggested that all cultures should be concerned with the development of characteristics associated with success in the domain of 'work,' and this concern would be related to evaluations on conscientiousness. Nevertheless, if there is an enigmatic domain of personality development (at least as it appears in parental descriptions of children), it is conscientiousness. As a total category, proportions of parental descriptions were low but highly variable by culture, ranging from 7 percent (USA) to an outlier of 19 percent (China). Chinese parents used almost three times as many descriptors of diligence, and twice as many descriptors of carefulness, as did US parents. Closer inspection shows that Chinese parents' descriptors were drawn from the low end of the dimension (e.g., not diligent), after the child was older than three years of age. What is enigmatic, perhaps, is the low proportion of conscientiousness descriptions relative to the increasing importance of the dimension with age of child in five of the seven countries studied. The outcomes for conscientiousness may reflect cultural differences in the value of education, and in the values of modesty and humility. Chinese parents seem to stress achievement motivation more than parents in the USA, and as a result may have been more critical. Describing one's own children in very positive terms may be especially unseemly for Chinese parents.

4. Future Directions

In the broad-brush overview presented here, it is possible to see the recent advances in theory and research on personality development in childhood. The advances are due in part to (a) efforts to find points of convergence, and to synthesize different perspectives on personality development; (b) the discovery of certain empirical regularities, both within cultures and across them; and (c) more sophisticated research techniques that permit the consideration of several variables at a time. In particular, we see increasing awareness that both culture-based, social learning environments and dispositional characteristics contribute to the personality development process. Important questions and issues remain, however, for the future.

We began this entry with a modern definition of personality as a structural integration of individual differences. Personality development theory and research have only begun to deal with the issue of organizational structures. Theoretical accounts of the development of personality structure are rare, but rarer still as systematic empirical evaluations of such theoretical accounts. So far, the best available research has demonstrated empirical links of variables taken

one at a time, which is no small achievement. This is some distance, however, from the theoretical description of personality as a structured integration. Furthermore, it could be argued that much of the personality development literature has yet to move from the assessment of reliability to the assessment of validity. Still missing from the personality development literature are systematic demonstrations of predictive validity to theoretically important external criteria. Mean differences in frequencies in personality descriptions across cultural groups or sex do not guarantee corresponding differences in overt behavior, or the prediction of overt behavior by personality. For example, Greek parents may use more agreeableness words to describe their children than do US parents, but do agreeableness differences predict choice of conflict strategies in a more differentiated way for Greek children than for US children? In a related vein, linking infant and toddler characteristics to later childhood personality is also promising, but it is not clear how (or even whether) early characteristics are foundational developmentally for later personality structure (but see Kochanska et al. 1998, Rothbart and Bates 1998). That is, early appearing temperaments and dispositions, and life experiences like parental divorce, may precede later personality, and may even predict later personality patterns. Such connections may not be causal or developmental in nature (e.g., Lewis et al. 2000). Is childhood in fact an especially formative period for personality development, or just another way station for the unfolding of a maturation-based personality system? Alternatively, is childhood just another social ecology to which each child must adapt, but with no long-term consequences for personality development? These questions go to the heart of personality development because they address the question of the origins and maintenance of continuity in persons across time. On an optimistic note, these limitations are less obstacles than incentives for future work on personality development in childhood.

Personality Disorders

1. General Considerations

Until the 1980s, both the scientific and the therapeutic aspect of personality disorders constituted a rather underdeveloped field despite their great significance for clinic and practice. Since the introduction of separate Axis II personality registration used in DSM-III (APA 1980) and the subsequent editions, DSM-III-R and DSM-IV (APA 1987, 1994), research and publication worldwide have been considerably stepped up, leading to the inception of professional journals and scientific societies devoted solely to the field of personality disorders. As of the beginning of the twenty-first century there is a veritable deluge of theoretical concepts and therapeutic methods.

More than in any other area of psychiatry, one still sees many inaccurate terms and concepts, and hard data on nosology, etiology, and pathogenesis of the various personality disorders remain rare. To be sure, there is a wealth of isolated pieces of etiological and pathogenetic knowledge on factors influencing the formation and progress of accentuated personality traits, but a comprehensive theoretical or empirical model remains as elusive as ever. We can therefore only address certain points and make some qualified references, as the exceedingly complex nature of the subject still does not allow any more definite statements.

'Personality disorder' is a value-free term which encompasses all those deviations from a normal personality development which require treatment. There are, necessarily, fluid borders to mental health on the one hand and mental disorder on the other.

Concepts with meaning similar or identical to personality disorder are psychopathy, abnormal personality, psychopathic development, psychopathic or dissocial personality, sociopathy, etc. In Sect. 3, the author will give an overview of the historical roots of

these concepts while also addressing recent diagnostic and therapeutic developments.

2. Terms and Definitions

The most comprehensive term in this field must surely be 'personality.' One of the most complex terms in our language, it can be defined in a variety of ways.

Popularly, personality is often used as an ethical-pedagogical value judgment to mean character or temper, as when referring to someone as a strong personality or a person of character. Moral judgments are likewise made, as when we say that all human beings are persons, but we do not mean that everyone is a personality, which is characterized by a conscious and sustained exercise of thought and will.

The current psychological and psychiatric definition of personality is: the sum of all mental and behavioural characteristics which make each of us a unique individual.

On the other hand, a personality disorder occurs if, due to degree and/or a particular combination of psychopathologically relevant features in any of these areas, there is considerable suffering and/or lasting impairment of social adaptiveness (Saß 1987). According to DSM-IV, only when personality traits are inflexible and maladaptive and cause either significant functional impairment or subjective distress do they constitute personality disorders (Table 1).

3. A History of the Concepts of Abnormal Personality

The concept of psychopathy arises from a confluence of views entertained by the French, the German, and the Anglo-American psychiatric traditions. Sociocultural factors caused these conceptions of psychopathy to develop more or less independently well into the twentieth century. The following section deals with all three traditions.

Table 1

General diagnostic criteria for personality disorder

A. A lasting pattern of inner experiences and behavior which deviates markedly from the expectations of the culture the individual lives in. This pattern is manifested in two or more of the following areas:

1. cognition (i.e., ways of perceiving and interpreting oneself, others, and events)
2. emotiveness (i.e., range, intensity, stability, and appropriateness of emotional response)
3. interpersonal functioning
4. impulse control

B. The pattern is inflexible and pervasive across a broad range of personal and social situations.

C. The pattern leads to clinically significant distress or impairment in social, occupational, or other important areas.

D. The pattern is stable and longstanding, and its onset can be traced back to adolescence or early adulthood.

E. The pattern is not better accounted for as a manifestation or consequence of another mental disorder.

F. The pattern is not due to direct physiological effects of a substance (e.g., drug or medication) or a general medical condition (e.g., head trauma).

3.1 French Concepts

Pinel's (1809) concept of *manie sans délire* includes instances of 'deranged personality' and can be looked upon as the beginning of the scientific study of personality disorder as a nosological entity. In the eighteenth century, all mental diseases were regarded as fundamental disturbances of the intellect. Pinel was one of the first to point out that in some disorders, the emotions were primarily involved. Nevertheless, the early nineteenth-century definitions of madness remained centered mostly around the intellect. Indeed, to this day, psychiatric phenomenology neglects the disorders of affect.

Esquirol (1838) developed the concept of monomania, a diagnostic category based on the partial, primary—and independent—involvement of the intellectual, emotional, and/or volitional functions of the mind, including states where a single behavioral disturbance became the sole diagnostic criterion for the condition (e.g., pyromania or kleptomania). Not surprisingly, monomania was one of the sources of the concept of psychopathy. Since its inception, the concept of monomania has been criticized on clinical and medicolegal grounds both in France and abroad.

Morel's (1857) idea of degeneration was a pseudo-biological account strongly tinged with the idea of original sin. He proposed that: (a) degenerative alterations are pathological deviations from the normal; (b) mental illness is mostly hereditary; and (c) degeneration is both quantitative and qualitative, i.e., new disorders may appear. According to Morel's model, all types of mental and neurological disorders can be traced back to one common hereditary origin. His idea of progressive and polymorphic degeneration was accepted as an explanation of mental illness.

3.2 Anglo-American Concepts

Prichard (1835) defined moral insanity as 'madness consisting of a morbid perversion of the natural feelings, affections, inclinations, temper, habits, moral dispositions and natural impulses without any remarkable disorder or defect of the interest or the reasoning faculties, and particularly without any illusion or hallucinations.' During the early nineteenth century, the word 'moral' had many uses, in the psychological sense chiefly to denote the affective and the conative (rather than the purely intellectual) functions.

The British concept of psychopathy was shaped by D. K. Henderson (1939), who saw 'psychopathic states' as a condition of 'constitutional abnormality.' In contrast to other (especially German) psychiatrists, he thought of constitution as deriving from both heredity and environment. There were three psychopathic states, the predominantly aggressive, the inadequate, and the creative. The former two were

characterized by antisocial traits and soon became part of the Anglo-American concept of personality disorder.

Rush (1812) was the first Anglo-American psychiatrist to study individuals whose disturbances were primarily characterized by irresponsibility and aggressiveness; who showed, as he put it, a 'moral alienation of the mind.' He believed that these reprehensible acts were the manifestations of mental disease, that they were unmotivated and driven by 'a kind of involuntary power.'

Partridge (1930) defined the concept of psychopathic personality as a persistent maladjustment which cannot be corrected by ordinary methods of education or by punishment. From Partridge on, the emphasis has been on description, and etiological speculation has taken the back seat. To this day, a view of psychopathy as sociopathy dominates Anglo-American psychiatry. A parallel concept, that of the antisocial personality disorder, appeared in DSM-III (APA 1980) and was kept in DSM-III-R (APA 1987) and DSM-IV (APA 1994).

3.3 German Concepts

In Germany, the concept of psychopathy embraces most forms of abnormal personality. The current German definition can be traced back to Koch, whose monograph *Psychopathische Minderwertigkeiten* [Psychopathic Inferiorities] (1891–93) was as decisive in shaping the concept of abnormal personality in Germany as Pinel's work was in France, Rush's in the USA, and Prichard's in Great Britain. German ideas of psychopathy also influenced French and Anglo-American views, especially after the 1930s, when many German-speaking psychiatrists and psychoanalysts emigrated to these countries.

Kraepelin's concept of psychopathy, influenced by the French theory of degeneration, formed the basis of Kurt Schneider's typology, and via the latter, of today's German doctrine of psychopathy. In successive editions of his textbook, Kraepelin elaborated on his concept of 'psychopathic states' as abnormal personality. He employed the term 'psychopathic personalities' in a predominantly social sense, including also innate delinquents, unstable liars, swindlers, and pseudo-querulous individuals.

During this period, there also appeared various 'systematic' typologies to draw 'psychopathic' categories from prototypic personality theories. Foremost amongst these is Kretschmer's *konstitutionstypologisches Modell* (1919). He suggested a specific correlation between body type and personality. Kretschmer (1921) and Ewald (1924) also introduced the concept of *Reaktionstypologie* to account for specific styles of dealing with experience. Systematic typologies lost influence after the publication of Schneider's monograph in 1923.

Kurt Schneider is known especially for his famous monograph *Die psychopathischen Persönlichkeiten* [The Psychopathic Personalities] (1923). He used a 'typological approach' to personality types and tried to avoid value judgments by not including antisocial forms of behavior. Schneider defines abnormal personalities as statistical deviations from an estimated average norm, although the concept of norm is poorly formulated in his work. In his model, eminently creative and intelligent individuals are also abnormal; hence, not all abnormal personalities could be said to have psychiatric implications. Schneider defined 'psychopathic personalities [as] those abnormal personalities that suffer from their abnormality or whose abnormality causes society to suffer.' It is very important to stress that Schneider did not consider psychopathy a form of mental illness, which by definition must be associated with a brain lesion or a recognized disease process. In this, he opposed Kretschmer and Bleuler, who believed that psychosis and psychopathy were just different degrees on the same spectrum of derangement. Schneider's doctrine influenced all subsequent typologies, and current classification systems include essential parts of his concept of psychopathy. The appendix to DSM-IV even includes the 'depressive type' to encourage further research on this subject.

4. Epidemiology, Course of Illness, and Prognosis

According to German and American studies, 3–10 percent of the general population meet the diagnostic criteria of a personality disorder. Compared to numbers in earlier manuals, these are rather high. However, simply meeting these criteria need not imply that the individuals in question are so dysfunctional and impaired as to require treatment.

Prevalence rates are much higher among unselected psychiatric patients. After the first classification systems appeared, clinical studies found surprisingly high frequencies for personality disorders—50–80 percent—while more recent studies reported prevalence rates of 40–60 percent on the average. Forensic-psychiatric random samples yielded prevalence rates of up to 80 percent. In a large-scale international WHO study (Loranger et al. 1994), 39.5 percent of 716 psychiatric patients examined showed at least one personality disorder according to ICD-10, individual prevalence rates falling between 15.2 percent (anxious personality disorder) and 1.8 percent (schizoid personality disorder).

Clinical experience has shown that increasing age and decreasing vitality tend to attenuate 'sharp' personality traits, especially those which seriously impair social functioning, such as inconstancy, antisocial behavior, and impulsiveness. Other traits can become sharper with advancing age, above all obstinacy and rigidity.

The prognosis depends on the particular type of personality disorder, on any eventual comorbidity, and on the degree of severity. Further prognostic factors are psychostructural maturity as well as the level of psychological and social functioning. Prognostically favorable characteristics are motivation, trust in others, flexibility, and insight into one's own role in difficulties with interpersonal contact. Cases are complicated by concomitant illness, especially addiction and affective disorders. Thus, the mortality rate for patients with personality disorders and substance abuse is three times that of patients with a single personality disorder (Bohus et al. 1999).

Generally speaking, the risk of suicide is three times higher for individuals with a personality disorder than for the general population, with borderline, narcissistic, and antisocial personality disorders showing the highest incidence. These groups also show the highest degree of psychosocial impairment, with deviant actions, decreased capacity for work, and deficient skills at establishing dependable interpersonal relations.

5. Diagnostic Problems

In view of the complexity of the concept of personality, it becomes clear that difficulties exist in distinguishing between a normal range of varying personality traits (as many as 1800 features have been identified which might aid in characterizing possible personality traits) and personality disorders which might be of psychiatric relevance. Towards the end of the twentieth century there has been a trend towards reducing the myriad personality traits to 3, 5, or 7 essential dimensions from which the individual variations can be derived (Table 2).

Interestingly, the factor structure of behavior and its abnormalities seems to be essentially the same in the general population and in clinical groups of behaviourally abnormal patients. The differences lie mainly in the degree and the particular combination of the various dimensions, not in a fundamental difference of personality traits.

Categorical classifications are based on somatic models where the various diseases can be clearly separated from each other; personality disorders, however, show fluid borders, both between the various types and towards normality. Dimensional personality models, developed especially for scientific research, measure degree—or severity—by means of trait factors and thus assign it a position corresponding to its extent along various dimensional axes. It must be kept in mind that there is no inherent qualitative difference in personality traits between the general population and clinical groups of patients with personality disorders, only a difference in degree or severity, or eventually in a particular combination of traits. By means of factor analyses, these personality models

Table 2

Factor models of dimensional personality description

3-factor personality models	5-factor personality models	7-factor personality model
Eysenck (1977) neuroticism extroversion psychoticism	Costa and McCrae (1990) extroversion neuroticism agreeability conscientiousness	Cloninger (1994) harm avoidance novelty seeking reward dependence persistence
Millon (1981) joy/pain self/other-centeredness activity/passivity	openness to new experiences	self-directedness cooperativeness self-transcendence
Widiger et al. (1994) free-floating anxiety/eccentric behavior assertiveness/dominance social integration	von Zerssen (1988) extroversion neuroticism aggressivity conscientiousness openness (devoutness)	
DSM-IV (1994) eccentricity dramatic affect fear		

Table 3

Classification of personality disorders

DSM-IV	ICD-10
paranoid	paranoid
schizoid	schizoid
schizotypal	—
antisocial	dissocial
borderline	impulsive
histrionic	histrionic
narcissistic	—
avoidant	anxious
obsessive-compulsive	obsessive-compulsive
not otherwise specified	not otherwise specified and others

reduce the myriad personality traits to a few essential personality dimensions, independent of culture, from which the individual variants may then be derived. However, given the clinical usefulness of the categorical approach, and hence the widespread hesitancy in abandoning it, recent efforts have tended more towards a synthesis of the categorical and dimensional elements.

The classification systems used today, which increasingly determine personality diagnosis, are the *Diagnostic and Statistical Manual of Mental Disorders, 4th Edition* (DSM-IV), published by the American Psychiatric Association (APA 1994), and the *International Classification of Diseases, 10th Edition* (ICD-10), published by the World Health Organization (WHO 1992). Both are used for making diagnoses, thus forcing clinicians, practitioners, and researchers

alike to opt for one of the two systems. While the two systems resemble each other in many aspects, there are others where they completely disagree. Table 3 gives an overview of the most important discrepancies (see *Differential Diagnosis in Psychiatry*).

6. Therapy of Personality Disorders

Following a thorough anamnesis, there are two main options: psychotherapy and therapy with psychopharmaceuticals. In detail:

6.1 Thorough Initial Examination

The general procedure in treating personality disorders follows the usual rules of psychiatry. It is important that a thorough initial examination be done, with an exact medical and psychiatric anamnesis. Due to the lacking self-dystonia, the patient's self-perception may be lower than in cases showing acute psychopathological symptoms. Hence, anamnesis by significant others can also be helpful in assessing social conflict when dealing with personality disorders.

6.2 Psychotherapy of Personality Disorders

In the psychotherapy of personality disorders, the choice of the therapeutic procedure will depend on the particular form of personality disorder, its severity, as well as any concomitant mental disorders. Currently accepted forms of therapy include: cognitive/

behavioral therapeutic and supportive techniques, depth psychology, disorder-oriented and interdisciplinary therapies with treatments for specific problem areas of a personality, pedagogic or psychogogic therapies, sociotherapy, and dialogue sessions for couples or families. An important element of every therapy is that disorder-related behavior and interaction abnormalities also be dealt with in the patient–therapist relation, so that a big step in the therapy will consist in opening up new self-awareness and possibilities of change to the patient via the therapeutic interaction itself.

Psychotherapy of personality disorders usually requires a long time, since it involves a gradual reshaping of long-lasting characteristics in the areas of experiencing, feeling, and social behavior. Short-term crisis intervention can also be helpful if the problematic personality traits bring situations to a head and cause social conflicts. Building up a regular, trusting relation is of great importance. The frequency usually chosen is one to two hours per week. Aside from discussing current life conflicts, exploring past issues is also important as it can outline the development of the personality traits which are at the root of the trouble.

Group therapy is well suited for many personalities (provided they are not seriously deranged) since observing other patients allows learning by example. The positive feedback or criticism from the other group members can reinforce desirable behavior and put undesirable behavior in perspective (see *Cognitive and Interpersonal Therapy: Psychiatric Aspects*).

6.3 Pharmacotherapy

The second important therapy for personality disorders, one which in recent years has been increasingly developed, consists in the use of psychopharmaceuticals. It rests on the assumption that personality disorders can also have a biological cause which may be either constitutional or due to functional anomalies which were acquired later.

The aim is to reduce the vulnerability to affective and cognitive dysfunctions neurochemically and to modify certain behavioral reaction patterns, the target symptoms or syndromes being:

- (a) the characteristics of the personality disorder (e.g., cognitive deficits, impulsive behavior, strong mood swings);
- (b) complications due to the personality disorder (e.g., suicidal tendencies, aggressivity towards others, deficient social skills); and
- (c) the axis I disorders associated with these (e.g., depressive or anxiety syndromes, compulsion, eating disorders).

The pharmacological treatment of personality disorders is by no means an alternative to psychotherapy. Rather, it is used in support and preparation for psychotherapy, as well as for crisis intervention (especially with suicidal tendencies).

Due to the dangers of side effects and habituation or dependence associated with it, long-term pharmaceutical therapy of personality disorders must always be viewed critically. Likewise, the therapist must be aware of the danger that the patient may start believing in external control or attribute therapeutic success solely to the action of the psychopharmaceuticals.

Moreover, there are special counterindications: alcohol and medicine abuse, social unreliability, bad compliance (incoming to therapy or in taking the medication). Due to the danger of late dyskinesias following long-term use, neuroleptics should be employed judiciously and substances of low or medium potency be considered. With benzodiazepines there is a particularly high risk of addiction, which is why they are generally not indicated for the treatment of personality disorders. Medication can also be tricky with some patients, who may harbor unrealistic expectations or fear to lose control. Due to these difficulties, such individuals may have to be admitted as inpatients before psychopharmaceutical therapy can be initiated (see *Psychotherapy and Pharmacotherapy, Combined*).

7. The Most Important Personality Disorders According to DSM-IV

This section offers classification of personality disorders, followed by an overview of the most important forms of abnormal personalities in DSM-IV. Please consult the manual for a complete list of the diagnostic criteria for the following personality disorders. The differential diagnosis refers solely to the Axis-I disorders (because of limited space).

7.1 Paranoid Personality Disorder

According to DSM-IV, persons with a paranoid personality disorder show a pattern of distrust and suspicion, reading malevolence into the motives of others without sufficient basis for that supposition. They often doubt the loyalty of their friends, partners, or associates and are reluctant to confide in others for fear that the information might be used against them. Persons with a paranoid personality disorder quickly react to perceived insults with excessive force, counterattacks, and/or long-lasting enmity. Mistakes are usually blamed on others. Persons with this disorder usually have recurrent suspicions regarding the fidelity of their spouse or partner. These persons are easily insulted, emotionally rigid, and persevering while at the same time appearing humorless and restrictive in their expression of warm emotions.

7.2 Schizoid Personality Disorder

The chief characteristics of the schizoid personality disorder are an inability to develop close emotional

attachments to others, seclusiveness, and a reduced capacity for emotional experience and expression in interpersonal settings. Schizoid personalities neither desire nor enjoy close relationships, have little, if any, interest in sexual experiences, and do not have friends or confidants. Persons with a schizoid personality disorder are shy, show emotional coldness and detachment, and are seemingly indifferent to praise or criticism. They take pleasure in few activities and distinctly prefer solitary ones. They may function adequately at work, especially if their job requires little social contact.

7.3 Schizotypal Personality Disorder

The schizotypal personality disorder is characterized by strong deficits in establishing interpersonal contact. Persons with schizotypal personality disorder show a pronounced fear of social situations and actively avoid them. They do not have close friends or confidants. Their interpersonal deficits are marked by acute discomfort with close relationships, constricted affect, cognitive and perceptual distortions, and eccentricities of behavior, as in their choice of dress and movement. Persons with this disorder often develop magical thinking and a belief in the occult, and sometimes ideas of reference or paranoid ideation may influence their behavior. Regarding language, there are unclear, strange, or stereotyped expressions and incorrect use of words, though not to the point of associative loosening and incoherence.

Phenomenological, biological, genetic, and outcome data (e.g., the Danish adoption studies) show a relation between schizotypal personality disorder and schizophrenia. Therefore, it is often considered a schizophrenia-spectrum disorder.

7.4 Antisocial Personality Disorder

The main characteristic of the antisocial personality disorder is a permanent and deep-seated tendency to violate and abuse the rights of others occurring from the age 15 years on. These persons show little introspection and self-criticism, lack empathy, show coldness, egotism, an exaggerated sense of entitlement, a paradoxical idea of adaptation, and weak or faulty social norms. Their behavior is marked by impulsiveness, unreliability, weak commitment, and absence of guilt feelings. They are practically beyond therapy and prognosis is generally unfavorable.

7.5 Borderline Personality Disorder

The borderline personality disorder shows a pattern of interpersonal and affective instability which often

leads to sudden, short-lived bursts of extreme mood swings. The affective outbursts usually take place under conditions which are perceived as threatening, such as real or imagined abandonment or rejection.

Especially characteristic for borderline personality disorder is an alternating lifelong pattern of impulsively inflicting harm on oneself or others, including self-inflicted wounds, bulimic binge-and-purge attacks, periods of excessive alcohol consumption, or fights. Repetitive suicide threats and attempts are common.

Unlike antisocial personalities, most patients try to restrain or suppress their impulses, although these attempts often fail. This leads to unpredictable swings between a tense holding back of affective impulses on the one hand and sudden outbursts on the other. Predominant emotions are dysphoria, anxiety, anger, and chronic feelings of emptiness.

Borderline personality disorder patients are furthermore characterized by a highly unstable image and perception of themselves, which can also include aspects of gender identity, deficient orientation and plans for the future, as well as indiscriminate choice of social groups or partners. In their unstable and intense interpersonal relationships they often alternate between extremes of idealization and devaluation (splitting). A last and important area are the transient, stress-related dissociative or (pseudo)psychotic symptoms or paranoid ideas (see *Borderline Personality Disorder*).

7.6 Histrionic Personality Disorder

The main characteristics of this personality disorder are a strong need to be at the center of attention and to gain recognition. Persons with histrionic personality disorder show a pattern of excessive emotionality with self-dramatization, theatricality, and coquetry that may be reflected in their style of speech, which is impressionistic and lacking in detail.

There is a tendency for affective instability and superficiality, displaying rapidly shifting emotions. Most patients are largely suggestible and unable to maintain a steadfast pursuit of goals or value orientation. They are thus inconstant, especially in relationships. Persons with histrionic personality disorder often interact with others in an inappropriate, sexually seductive or provocative manner, using their physical appearance to draw attention to themselves. Relationships are often considered to be more intimate than they actually are.

Also clinically relevant, though uncommon, are the sometimes drastic 'pseudohysterical' cases showing aggravation, conversion, dramaticism, and improper behavior.

Manic states may be accompanied by exaggerated expression of emotion and impressionistic behavior,

but can be distinguished from histrionic personality disorder by the temporary nature of these symptoms and, of course, the presence of other specific/typical symptoms of mania.

7.7 Narcissistic Personality Disorder

According to DSM-IV, individuals with a narcissistic personality disorder have an exaggerated sense of self-importance, are preoccupied with fantasies of grandiosity or superiority, and require excessive admiration. They believe that they are 'special' and can only be understood by other special people.

Patients with narcissistic personality disorder tend to exploit others involuntarily, thinking that their own qualities and abilities entitle them to special treatment. There is a lack of empathy which becomes obvious in the unwillingness to identify with the feelings and needs of others. Further symptoms are a basically fragile self-esteem and feelings of envy and distrust towards others. With a clearly increased self-awareness and egotism, social discomfort and fear of negative opinions predominate. A particular problem is a tendency for depressive crises and resolute suicidality following an imagined insult.

7.8 Avoidant Personality Disorder

The avoidant-insecure personality disorder is characterized by a pervasive pattern of low self-esteem and hypersensitivity to negative evaluation. Despite their strong wish for affection, persons with avoidant-insecure personality disorder avoid social relations, being insecure, shy, tense, and anxious. Their feelings of inferiority and inadequacy in social contact lead to a severe restriction of their social skills and roles, causing them to be reluctant to take personal risks or to engage in any new activities because they may prove embarrassing. Patients with avoidant personality disorder often show restraint with intimate relationships out of a strong fear of shame.

7.9 Dependent Personality Disorder

The dependent personality disorder is characterized by an overpowering feeling of not being able to conduct one's own life. With a self-image of weakness and helplessness, patients will seek support from others in all situations, especially from their partners. Persons with a dependent personality disorder need others to assume responsibility in most major areas of their life. They have difficulties doing things on their own or making everyday decisions without advice from others, and fear that expressing disagreement

might result in a loss of support or approval. This leads to submissive behavior, sometimes to the point of being self-effacing and obsequious. In a relationship, these patients experience a constant fear of loss and abandonment, and urgently seek out somebody for support and care when a close relationship ends. They further show a cognitive distortion known as catastrophizing, which is a fearful and exaggerated estimate of the worst possible consequences of the relation ending.

7.10 Obsessive-compulsive Personality Disorder

The main characteristics of the obsessive-compulsive personality disorder are conscientiousness, perfectionism, conformism, and devotedness to work, which can be overvalued to the point of adversely affecting professional productivity and interpersonal relationships. They dislike teamwork or delegating tasks unless the others conform exactly to their way of thinking or acting. These persons show a severity and rigidity both with themselves and with others which often interferes with social functioning. They are overconscientious, inflexible, and rule-minded about matters of morality or ethics.

Obsessive-compulsive personalities are unable to separate the important from the unimportant (e.g., they cannot bring themselves to throw away old, worthless objects even when these have no sentimental value) and they have an inability to make decisions. Where money is concerned, they are miserly both with themselves and with others.

Of great importance are the interactions between the obsessive-compulsive personality disorder and depression. On the one hand, obsessive-compulsive personality traits can intensify during depression or first become disturbing, as in the form of depressive insecurity or difficulties in making decisions; on the other hand, obsessive-compulsive behavior can lead to difficulties, and hence to reactive depression, where obsessive-compulsive personality traits and depressive symptoms are closely interwoven.

7.11 Personality Disorders not Otherwise Specified

This category applies to personality disorders which are not designated by a DSM-IV diagnosis, but which cause clinically significant distress or impairment. It may also be used when the features of more than one Axis II disorder are present but the full criteria for any one disorder are not met. It also includes the depressive and passive-aggressive (negativistic) personality disorder, which are actually found in the appendix to DSM-IV, being currently under research to determine whether they should be included in DSM-V or not.

8. Concluding Remarks

Concluding, it should be noted that that all typologically arranged classifications of personality disorders are merely conventions. By giving a good description of the reality of life, they may acquire a certain plausibility, self-evidence, and clinical usefulness. A nosological diagnosis and therapy of personality disorders can only be expected for special forms, and even then only as long as it can be shown that they were caused by illnesses.

Most personality disorders, however, lie at the fringe of mental health. Instead of pathological processes, one has to deal with difficult developments in life due to a strained constitution and biography. First and foremost, these people need psychotherapeutic and psychogogic support. Far more than in mental illness, the manifestations in personality disorders are in great part shaped by such phenomena as will, decision-making, self-control, temper, intentionality, bearing, and character. Even more than mental illness, personality disorders require the biological and the psychopathological planes to be complemented by an anthropological dimension.

Personality Psychology

Personality psychology is the scientific study of the whole person. The goal of personality inquiry is to provide a scientifically credible account of human individuality. Such an account considers aspects of human nature (how a person is like all other persons), individual differences between people (how a person is like some other persons), and individual uniqueness

(how a person is like no other person). A full account of human individuality, furthermore, must situate a person's life in the biological, social, cultural, and historical contexts that give that life its meaning. This article will present a brief history of the field of personality psychology, a review of recurrent issues and controversies that have preoccupied personality psychologists, and a consideration of current and projected future research and theorizing in the field.

1. History

The roots of personality psychology can be traced back to the ancient Greeks. A pupil of Aristotle, Theophrastus (c. 300 BC) composed character sketches such as 'the flatterer' and 'the penurious man,' each of which personified (often in a humorous way) a particular personality trait. The Greek physician Galen (AD 130–200) is often credited with proposing the first taxonomy of personality traits, distinguishing among the sanguine, choleric, phlegmatic, and melancholic temperaments. It was not until the late nineteenth and early twentieth centuries, however, that scientists developed reliable methods for assessing individual differences in traits. Building on the pioneering work of Francis Galton and Alfred Binet on mental testing and spurred by the mobilization of large military forces in World War I, psychologists began to invent self-report, multi-item tests to assess individual differences in personality functioning. At about the same time, Sigmund Freud, Carl Jung, Alfred Adler, and other psychoanalytic theorists offered a strong alternative perspective on human individuality, underscoring the unconscious motivational dynamics that structure human lives and make for neurosis and conflict in human affairs.

The psychometricians and the psychoanalysts represented two very different intellectual traditions for personality psychology, both rooted in the nineteenth century. In the spirit of natural science inquiry (*Naturwissenschaften*), the former emphasized the precise quantification of common traits, readily assessed through conscious self-reports and manifest in observable behavior across many different persons. By contrast, Freud and the psychoanalysts offered a more holistic, clinically informed, and intuitive approach, consistent with the *Geisteswissenschaften* (human sciences) movement in the nineteenth century, proposing that the person is a complex and uniquely patterned whole. In the first authoritative textbook for personality psychology, Gordon Allport (1937) proposed that the two intellectual traditions might be reconciled within a single science of persons. Laying out an ambitious agenda for personality inquiry, Henry Murray (1938) published a landmark volume that drew heavily on the psychoanalytic tradition while proposing new methods for measuring personality traits, needs, and other features of human

individuality. The writings of Allport and Murray helped to establish personality psychology as an identifiable discipline in the social and behavioral sciences in the 1930s.

1.1 The Development of Personality Theories

By the mid-1950s, the field of personality psychology was dominated by a number of competing grand theories. Each theory offered a comprehensive portrayal of human individuality, specifying fundamental motivations, a structure for understanding individual differences, principles of personality development, and in some cases a corresponding clinical technique for personality change (e.g., a brand of psychotherapy). Beginning with Hall and Lindzey (1957), personality textbooks typically organized the field in terms of these grand theoretical rubrics, each of which offered its own agenda for personality research.

The largest number of theories came out of the psychoanalytic tradition. Freud's seminal theory, articulated mainly between the years 1895 and 1930, proposed that all human behavior is determined by unconscious forces over which the individual has little control, forces that typically stem from sexual and aggressive drives. Rooted in instinct and early childhood experience, unconscious wishes, urges, and drives seek expression in a social environment that is predicated on the suppression of human urgings. The conflicts between internal urges and external constraints make for anxiety, defense, and a panoply of personal adaptations that define human individuality. Variations on these themes were played out in a number of other psychoanalytic theories, beginning with Jung's and Adler's rival approaches. While Jung proposed that individuality stems from each person's exploration of an evolutionarily rooted collective unconscious, Adler emphasized conscious aspects of human functioning and the prime motives of power and social interest. Around the time of World War II, neo-Freudian theorists like Karen Horney and Eric Fromm sought to link individual development to cultural factors, while Erik Erikson broadened Freud's psychosexual focus to include psychosocial issues that confront the person across the human lifespan. Moving in a different direction, postwar object-relations theorists such as W.R.D. Fairbairn and psychoanalytic self-theorists such as Heinz Kohut redoubled efforts to explore the most primitive intrapsychic factors laid down in the first two years of life and played out most importantly in the mother–infant bond.

Outside the psychoanalytic tradition, grand personality theorists came in behaviorist, trait, and humanistic/phenomenological varieties. Seeking to operationalize Freudian concepts in terms amenable to midcentury behaviorism, Neal Miller and James Dollard developed an influential social learning theory

of personality, which was followed by more cognitively based theories offered by Julian Rotter and Albert Bandura. Employing the method of factor analysis of personality trait scales, Raymond B. Cattell and Hans Eysenck conceived of personality in terms of a finite set of objectively defined traits. Eysenck's three-trait scheme—highlighting introversion–extraversion, neuroticism, and psychoticism—proved especially influential. Finally, a wide range of grand theories were built around a humanistic vision of the person as a more-or-less rational being, endowed with rich conscious experience and motivated to actualize his or her own potential. Included here were Allport's own theory, the humanistic approaches offered by Carl Rogers and Abraham Maslow, George Kelly's personal construct theory, and existential personality theories offered by Rollo May, Victor Frankl, and others.

1.2 The Elaboration of Constructs

Postwar personality psychologists borrowed liberally from the grand theories to identify individual-difference variables—or 'constructs'—that could be reliably measured through self-report scales, ratings, behavioral observations, and other techniques, and then used in hypothesis-testing research. Popular constructs of the 1950s and 1960s included anxiety, achievement motivation, authoritarianism, extraversion, ego resiliency, field independence, and locus of control. Investigators designed programs of study to examine the antecedents, consequences, and correlates of these individual differences in personality. Around each construct, then, developed a nomological network of findings—a body of research that elaborated the construct and defined its role and significance in personality functioning. With increasing specialization and the emphasis on discrete constructs, the field of personality psychology began to turn away from the grand theories to focus on problems in the measurement of individual differences. Omnibus personality inventories, such as the Minnesota Multiphasic Personality Inventory (MMPI) and the California Psychological Inventory (CPI), measured many different variables at once. But many postwar researchers preferred to focus on one construct at a time, refining measures and articulating in great detail that construct's nomological net.

The field of personality psychology experienced a crisis in confidence in the late 1960s and 1970s. Some critics lamented the decay of interest in integrative theory and the obsessive focus on constructs over persons. Others, most notably Walter Mischel (1968), argued that personality constructs themselves were not good predictors of behavior. In Mischel's view, social situations account for vastly more variance in human behavior than do individual differences in personality traits. What was often called the 'trait versus situation debate' preoccupied the field in the

1970s and early 1980s. As the debate died down, proponents of both sides seemed to agree that personality theories and research need to explicitly embody interactionism—the idea that behavior is always a function of the interaction of the person (e.g., traits) and the environment (e.g., situations). In the 1980s and 1990s, furthermore, strong evidence was adduced for the efficacy of personality constructs. First, studies increasingly showed that traits do predict general trends in behavior over time and across different situations. Second, longitudinal studies showed that individual differences in traits are often remarkably stable over long periods of time. Third, evidence from behavior genetics, especially studies with twins, showed that most personality traits exhibit at least moderate heritability. And fourth, some consensus in the field began to emerge concerning the number and kind of basic personality traits. Based on extensive factor-analytic studies, the popular Big Five conception proposes that traits cluster into five different factors, which may be labeled extraversion, neuroticism, conscientiousness, agreeableness, and openness to experience.

2. Perennial Issues and Controversies

In his first textbook, Allport (1937) foresaw a number of issues that were destined to stimulate recurrent debate in the field of personality psychology. The one that most preoccupied Allport himself was the tension between nomothetic and idiographic approaches to personality inquiry. While nomothetic approaches seek to establish general laws of behavior that apply across persons, idiographic approaches, as embodied in the case study, focus on the unique or characteristic patterning of an individual person. The vast majority of published research in personality psychology is nomothetic, typically involving the testing of hypotheses about personality constructs and processes. But if the field itself is supposed to be concerned with human individuality, Allport argued, then some form of idiographic inquiry must be included. Skeptics have countered that the results of single-case studies cannot be generalized, and thus have little scientific value. But proponents of idiographic approaches maintain that case studies are often excellent arenas for hypothesis discovery, for applying general theories, and for illuminating complex personality organization. Along with Allport and Murray, Robert White (1952) championed the intensive study of individual lives. Recent years have witnessed a resurgence of interest in idiographic approaches and considerable optimism about integrating them with more conventional nomothetic methods.

A forerunner to the 'trait versus situation debate' of the 1970s was Allport's identification of the problem of generality versus specificity in behavior. To what extent is a person's behavior generally consistent across situations, as opposed to being specific to the

vagaries of particular situations themselves? Mischel (1968) argued that Allport and most other personality psychologists overplayed the generality idea, expecting their constructs to predict general trends in behavior across many different situations. In Mischel's (1968) view, the empirical data were much more supportive of a specificity position. Although trait constructs have regained their currency in recent years, many personality psychologists have retained a healthy skepticism about cross-situational generality, and some have proposed that some personality constructs themselves need to be defined in contingent, situational terms.

A third issue concerns measurement. The most popular personality measures have always been self-report questionnaires. But many critics have argued that such measures are unable to assess especially subtle, implicit, or unconscious aspects of human individuality. As an alternative, some have championed projective techniques, wherein the person responds freely to ambiguous cues (e.g., inkblots, story scenes). For example, David McClelland (1961) built a highly successful research program around the assessment of achievement motivation in imaginative stories told to picture cues (the Thematic Apperception Test, or TAT). Others, most notably Jack Block (1971), refined Q-sort rating procedures that bypassed self-report for the evaluations of expert judges. While a plethora of measurement techniques may be seen in the field today, the self-report questionnaire, nonetheless, remains the coin of the realm.

A fourth controversy is the often-observed disconnect between grand personality theories and construct-based personality research. While some argue that a good deal of personality research has been directly or indirectly inspired by the grand theories, others contend that the grand theories should be dismissed as historical artifacts. The controversy is especially acute with respect to psychoanalytic theories. Many Freudian ideas, for example, have proven resistant to empirical scrutiny (e.g., the Oedipus complex) or have been jettisoned as outdated or just plain wrong (e.g., the death instinct). By contrast, some ideas that have traditionally been associated with psychoanalytic approaches have become incorporated into mainstream psychological research. Of most importance in this regard is the now generally accepted notion that a good deal of human information processing occurs in an automatic, implicit, and nonconscious manner. Thus, while psychoanalytic theories have exerted a strong impact on Western thinking more generally, their current and future status in personality psychology appears ambiguous at best.

3. Current and Future Trends

The wide range of research and theorizing that currently characterizes the field of personality psychology may be organized into three different levels or

arenas of human individuality: dispositional traits, characteristic adaptations, and integrative stories. The first domain considers individuality from the standpoint of general, cross-situational tendencies; the second examines more situationally and contextually grounded aspects of persons; and the third encompasses efforts to understand individuality in the more idiographic sense of how the person understands his or her life in toto.

3.1 Dispositional Traits

Dispositional traits are those relatively general and nonconditional aspects of human individuality that go by such names as 'extraversion,' 'friendliness,' 'depressiveness,' and 'conscientiousness.' Each trait is viewed as a bipolar, linear dimension upon which individuals can be said to differ. For example, research has shown that people scoring at the high end of the extraversion trait are viewed by others as especially sociable and fun-loving, typically attend more social events, are more sexually active, and report higher levels of positive affect in everyday life, compared to people scoring at the low (introverted) end of the trait (e.g., Eysenck 1967). Evidence for the predictive efficacy of trait scores is growing, with the strongest data coming for aspects of extraversion (sometimes reconceptualized as positive affectivity) and neuroticism (sometimes reconceptualized as negative affectivity).

Psychophysiological experiments have begun to document possible linkages between neural systems and individual differences in traits. For example, Jeffrey Gray and others have suggested that individual differences in extraversion/positive-affectivity may be linked to a behavioral activation system in the brain, responsible for motivating behavior aimed at achieving goals and obtaining positive emotional rewards. These kinds of advances, along with growing evidence for longitudinal consistency and heritability of broad traits, help to underscore the field's conviction that dispositional traits are fundamental to a scientific account of human individuality (see McCrae and Costa 1990, Wiggins 1996).

Increasingly, research on personality traits has become subsumed within the Big Five framework. While most of this research focuses on individual differences among well-functioning adults, recent efforts have also been made to reconfigure psychopathology in terms of (extreme) scores on personality traits. Individual differences in infant and childhood temperament, assumed to be strongly driven by genetic differences, have also been conceptually linked to the five-factor taxonomy. And some theorists have speculated about how individual differences in Big Five traits reflect varying strategies for solving fundamental social tasks that humans have perennially faced over the course of evolution. The integration of trait psychology with evolutionary theory would appear to be a promising direction for the future.

3.2 Characteristic Adaptations

Despite substantial progress in trait research in recent years, there would appear to be considerably more to personality than traits. While traits are useful for predicting and understanding consistent, cross-situational differences in people, they are less effective in the explanation of more particular, contextually anchored behavior. Accordingly, personality psychologists have proposed a host of motivational, developmental, and strategic constructs that are contextualized in time, place, or social role. These include particular motives and goals (e.g., the power motive), life tasks (e.g., the intimacy life task), relational styles (e.g., secure attachment style), defense mechanisms (e.g., projection), coping strategies (e.g., emotion-focused coping), values (e.g., dogmatism), developmental issues (e.g., generativity), self-schemas (e.g., possible selves, self-with-other representations), and the like, all of which may be grouped under the generic rubric of characteristic adaptations. If traits sketch an outline of human individuality, characteristic adaptations begin to fill in some of the details. More contingent and delimited than dispositional traits, characteristic adaptations speak to what a person wants or fears, often during particular periods in life or within particular domains of action, and what life methods the person may use to get what is wanted or to avoid getting what is not wanted at a particular time, in particular places, and/or with respect to particular roles.

While trait approaches have their historical roots in the grand factor theories offered by Eysenck and Cattell, studies of characteristic adaptations connect more readily to theories emphasizing human cognition, motivation, and development. In that they address especially concrete issues that can be observed in everyday adaptation to stress and challenge, moreover, characteristic adaptations speak a language that is compatible with the concerns of many clinicians. They also appear to shed light on proximal personality processes by specifying what cognitions or emotional states may give rise to particular behaviors. Recent years have witnessed considerable progress in the study of a wide range of characteristic adaptations (Pervin and John 1999), but the field has yet to offer a comprehensive framework, akin to the Big Five, for organizing these far-flung constructs and research programs. In a general sense, though, most adaptations link directly or indirectly to the two great domains of social life—love and work—or what David Bakan termed ‘communion’ and ‘agency.’

3.3 Integrative Stories

Since the time of Allport, some personality psychologists have maintained that while conventional personality constructs such as traits and characteristic

adaptations are useful for predicting behavior and accounting for individual differences, they are unable to account for the integrative nature of personality functioning and the sense of a person’s wholeness. Broader concepts such as self, ego, and character structure have often been invoked to refer to this integrative, holistic quality. For example, Jane Loevinger (1976) proposed that the ego is the master synthesizer of subjective experience, and she developed a rigorous program of research to operationalize stages of ego development through the coding of sentence-completion tests. More recently, a number of theorists and researchers have proposed that people synthesize their own experience into personal stories and that such internalized and evolving narratives of the self provide human lives with unity, purpose, and meaning. Silvan Tomkins, Dan McAdams (2001), and Hubert Hermans have all developed narrative theories of personality that attempt to account for human individuality in terms of the different kinds of life stories that people construct. This movement recalls Allport’s emphasis on the idiographic, and the study of lives tradition championed by White and others. But it adds a more nuanced understanding of the psycholiterary aspects of social life, especially under conditions of cultural modernity and postmodernity, and it proposes agendas for nomothetic research whereby individual differences in life narrative form and content can be operationalized and subjected to hypothesis-testing research.

In sum, current research and theorizing in personality psychology suggest that personality itself may be viewed as a patterning of dispositional traits, characteristic adaptations, and integrative life stories, evolving over time and complexly situated in a cultural and historical milieu.

Personality Psychology: Methods

All empirical research methods in psychology are concerned with the measurement of variation and covariation. Three methods for studying three types of variation and covariation can be identified. Experimental methods discern how behavior and experience vary across different environments. Developmental methods describe how behavior and experience vary over time. Finally, differential methods measure relatively enduring differences in characteristics of persons and the covariation among these differences. Although personality psychology occasionally employs experimental and developmental methods, its primary use of differential methods defines its distinctive position in psychology (Cronbach 1957). The specific methods used by personality psychologists can be further defined by (a) the type of individual differences under study, (b) the source of information about these differences, and (c) the purpose of assessing individuals' distinguishing attributes.

1. Types of Differences Measured

Gordon Allport's (1937) definitive etymological analysis of the term 'personality' finds that *persona*, the Latin root of 'personality,' originally referred to a mask worn by actors, and thus connoted a false or superficial appearance. Before long, however, *persona*

also came to designate more substantial attributes that qualify a person to perform particular roles. Today, 'external' and 'internal' aspects of personality continue to be distinguished. Ordinary-language descriptions of personality often refer to external social impressions. Trait terms representing these impressions tend to be broad and evaluative (e.g., nice, charming, nasty, irritating), and sometimes metaphorical (cold, prickly, warm, slick). Social impressions are explained by observable behavioral traits. For example, to impress others as 'warm,' a person must consistently smile, make eye-contact, talk tenderly, express affection, and show kindness and sympathy. External (social and behavioral) aspects of personality are typically measured by observer judgment (see Sect. 2.2).

Behavioral consistencies, in turn, are explained by 'inner' traits that guide and motivate behavior. Inner traits that refer to persistent thoughts, expectations, attitudes, thinking styles, and mental abilities are called 'cognitive traits.' Inner traits involving recurring feelings and emotional dispositions are called 'emotional' or 'motivational traits.' Personality psychologists often rely on the self-report method (see Sect. 2.3) to assess inner traits. Cognitive styles and competencies (e.g., creativity), are typically assessed by performance tasks (see Sect. 2.4).

2. Types of Individual Differences Data

Differential methods can be organized according to the types of the data one can use to study individual differences. The acronym LOST conveniently summarizes the four major types of individual differences data: life events, observer judgments, self-reports, and tests, or L-data, O-data, S-data, and T-data (see Block 1977).

2.1 L-data: Life Events

'Life events' refer to relatively objective facts about people that are often a matter of public record. Some examples are birth date, number of years of education and degrees obtained, marital status and number of children, occupational record, church attendance, hospitalizations, membership in societies, criminal convictions, leadership positions, and property ownership. Although life event information is often actually obtained by self-report methods (Sect. 2.3) its factuality can be independently verified. Research indicates a very high correlation between self-reported and independently verified life events, even under highly evaluative conditions such as applying for employment.

In both applied (see Sects. 3.1 and 3.2) and basic (see Sect. 3.3) personality research, life events are sometimes used as criteria to be predicted by other types of personality data and sometimes as predictors themselves. When gathered by self-report, L-data is interpreted according to self-report methods (Sect. 2.3).

2.2 O-data: Observer Judgments

Observer judgments are a fundamental source of information about external traits for two reasons (Block 1978, Hofstee 1994). First, an observer's judgment of external traits is direct and noninferential. Second, idiosyncratic biases and errors of judgment tend to cancel out when judgments are averaged across multiple observers. This means that even inner traits may be more validly assessed by observer judgments than self-reports, despite an individual's privileged access to his or her inner thoughts and feelings (Hofstee 1994).

2.2.1 Retrospective, integrative judgments versus one-time, direct observation. Observer judgments are often made by acquaintances who use their past knowledge to summarize their perceptions of someone's personality. Concern about potential distortions and memory limitations involved in making retrospective judgments lead some psychologists to favor direct behavioral observation. Despite potential distortions, retrospective judgments are more likely than single encounters to produce the representative sampling necessary for accurately assessing relatively enduring characteristics of individuals (Kenrick and Funder 1988).

2.2.2 Normative and ipsative frames of reference for observer judgments. For observer judgments to indicate what is distinctive about someone's personality, the judgments must be compared to some reference point. Take, for example, a study in which observers record from behind one-way glass instances of different types of behavior in a nursery school classroom over a period of one year. At the end of the year, a particular behavior count by itself—say 42 acts of aggression—is insufficient for describing a child as relatively aggressive or nonaggressive. A normative frame of reference would compare the number of aggressive acts for that child to the average number of aggressive acts across all children. An ipsative frame of reference compares the number of aggressive acts for the child to all other types of acts recorded for that child.

In retrospective observer judgments, judges are often instructed to compare a person to people in general with a rating scale. The middle point (e.g., '3' on a 1–5 rating scale) represents a theoretical normative reference point (i.e., people in general), while greater numbers represent higher levels of the trait and lesser numbers lower levels. Unipolar rating scales are anchored by a single trait word at the high end, while bipolar scales are also anchored with the psychological opposite at the low end (e.g., 'thoughtful' vs. 'inconsiderate'). Defining the anchors with concrete, descriptive phrases instead of abstract adjectives improves measurement validity. Often scores on several

related rating scales will be averaged to produce an overall score on a trait. For example, broad extraversion versus introversion might be assessed by the average of ratings on more specific scales such as talkative vs. silent, outgoing vs. reserved, and so forth.

When interpreting rating scores, psychologists need to consider whether to take the numerical score at face value. For example, a rating of 4 on a 1–5 scale of thoughtfulness is above the theoretical norm of 3, but if the computed average rating for a large group of people is 4.5, a rating of 4 could be interpreted as a relatively low level of thoughtfulness. This problem is further complicated when some judges restrict their ratings to one portion of the scale. A 5 might actually indicate a much higher value from a judge who assigns mostly 3s than from a judge who assigns mostly 4s and 5s.

Psychologists unwilling to accept scores at face value will recalibrate all of a judge's ratings with respect to the mean of all ratings made by that judge. This process is called 'ipsatizing' scores. Some rating procedures expressly call for ipsative assessment in the act of judgment itself. For example, judges using the California Q-set (Block 1978) are required to sort 100 personality descriptions into nine categories following a specified distribution (five descriptions in each of the extremely characteristic and uncharacteristic categories, eight descriptions in each of the quite characteristic and uncharacteristic categories, and so forth, to 18 characteristics in the relative neutral or unimportant category).

Formats other than rating scales for observer judgment of personality include questionnaires and adjective checklists. Items in some personality questionnaires are phrased in ways that allow either self-report (Sect. 2.3) or observer judgment. Adjective check lists contain a set of adjectives that judges check if they believe them to apply to the person being judged. Scores on adjective check lists are computed by counting the number of judges who check a particular adjective and/or by summing the checks for a group of adjectives considered to measure the same trait.

Factors that potentially limit the validity of observer judgments include misleading communications, stereotypes, and gossip about those being judged; unfairly positive or negative attitudes from judges who like or dislike the targets; and insufficient knowledge due to judges knowing the target only in certain roles and settings. These limitations and methods for overcoming them are discussed by Block (1978), Hofstee (1994) and Kenrick and Funder (1988).

2.3 S-data: Self-Reports

The two basic types of self-report instruments are projective tests and objective questionnaires. In projective testing, respondents are asked to finish incomplete phrases or construct stories about intentionally ambi-

guous images. Following guidelines developed by the test author and community of test users, psychologists score the respondent's protocol for psychological themes. Proponents of projective tests claim that these instruments are able to tap deep, unconscious needs and motives; critics insist that scoring projective protocols is too subjective and unreliable. Research indicates that carefully designed projective tests can be as reliable and valid as objective measures.

Personality questionnaires (Angleitner and Wiggins 1986) rarely consist of questions anymore. Instead, questionnaire items are statements about one's self and other people. Respondents express how much they agree with each statement or the degree to which they think the statement applies to them. The most comprehensive personality questionnaires contain several hundred items. Any subset of items within a personality questionnaire that is scored for a particular trait is called a 'personality scale.' The major personality questionnaires contain as many as several dozen different scales. Items are collected into scales and responses to items are scored according to one of four strategies outlined below: empirical, rational-intuitive, theoretical, or factor-analytic.

2.3.1 Empirical scales. Paul Meehl (1945) argued that psychologists would be naively optimistic to take questionnaire item responses at face value or to attempt to judge their hidden psychological meanings expertly. More prudent, he suggested, would be to treat each item response as a bit of behavior whose meaning must be determined by its empirical correlates. Empirical scales are constructed by locating all items on a questionnaire that tends to be answered differently by two groups known by other methods to differ on a particular personality trait. A person's score on an empirical scale is defined by the number of responses that match the responses given by one of the groups used in original scale construction. That is, if a person answers many items the same way as a group of people known to be aggressive, that person is considered likely to be aggressive also.

2.3.2 Rational-intuitive scales. The rational-intuitive approach to personality scales suggests personality traits can be assessed straightforwardly by items whose content, according to common sense, seems relevant to the trait (Wolfe 1993). Thus, a person who endorses items such as 'I am an aggressive person' and disagrees with items such as 'I never get in fights' would receive points on a rational-intuitive personality scale of aggressiveness. The obviousness of rational-intuitive scales perennially raises concerns about self-enhancement (exaggerating socially desirable traits and denying undesirable traits), but research indicates that respondents self-enhance on personality questionnaires no more than they do in everyday life. Furthermore, research indicates that

rational-intuitive scales validly predict relevant criteria as well as scales constructed by any other method.

2.3.3 Theoretical scales. Like rational-intuitive scales, theoretical scales are comprised of items whose content is judged to be relevant to the personality characteristic being assessed. The difference is that the relevance is not apparent to common sense and can only be seen by professionals versed in a particular theory. For example, the theoretical items 'I am fascinated by fire,' 'I would do anything on a dare,' 'My father and I always fought,' 'I own a gun,' and 'Women find me charming' seem unrelated to common sense, but, to a Freudian, these are items likely to be endorsed by a man with a phallic personality character resulting from an unresolved Oedipal conflict.

2.3.4 Factor-analytic scales. Factor-analysis is a statistical method for identifying clusters of items that tend to be answered the same way. This method, like the empirical method, begins with a large set of items that are administered to a group of respondents. If respondents who agree with item 'A' also tend to agree with items 'B,' 'C,' 'D,' and so forth, these items are deemed to measure the same psychological trait (Briggs and Cheek 1986). The nature of the trait is normally determined by rational-intuitive inspection of the content of the items. Factor analysis can be applied to scales as well as items, and factor analytic research has repeatedly indicated that much of the content of personality falls into five broad factor domains: extraversion, agreeableness, conscientiousness, emotional stability, and a fifth factor variously called intellect, imagination, or openness to experience. Many psychologists regard the 'Big Five' or 'Five-factor model' (Wiggins 1996) as a major integrating focus for future research.

2.4 T-data: Laboratory Tests

Assessing personality by testing respondents in laboratories or other controlled conditions is motivated by two interests. The first is establishing objective, replicable procedures that cannot be affected by biases and errors potentially found in observer judgments or self-reports. In particular, the measurement of involuntary reactions such as changes in electrodermal conductivity or heart rate to assess anxiety, or pupil dilation to assess interest, is seen as a way of circumventing dissembling that can occur with self-reports. Unfortunately, as Block (1977, 1978) points out, T-data are always indirect measures of personality, and laboratory tests that might seem to be reasonable measures of personality have a record of failing unpredictably.

The second motivation for using laboratory tests is the particular suitability of such procedures for measuring certain traits. Laboratory tests are particularly apt for assessing cognitive performance variables. For example, a personality theory built around the mental accessibility of different concepts would naturally be tested by measuring reaction time to words representing different concepts. Cognitive styles are almost invariably measured by performance tasks.

Personality theories that attempt to explain mental or behavioral differences in terms of underlying biological differences also require laboratory facilities to assess those differences. In addition to traditional psychophysiological recordings, new laboratory tests for measuring the physical basis of personality include biochemical assaying, positron emission tomography and functional magnetic resonance imaging. Details of these methods can be found in sources such as Davidson (1999), and Pickering and Gray (1999).

3. Three Purposes of Measurement

The three major purposes for measuring individual differences are: (a) making decisions about people, (b) helping people make decisions, and (c) conducting basic research. All three cases involve prediction (for further information see Wiggins 1973). In decision-making, personality assessments are used to predict how an individual person will think, feel, behave, or be perceived by others if various courses of action are pursued. In research, predictions are made about how different forms of individual differences are related to one another.

3.1 Making Decisions About People

In clinical and counseling psychology, personality scores are used to predict what course of therapy will best help persons with psychological problems. In personnel psychology, personality scores are used to predict which individuals will perform best if hired and placed in particular jobs. Some applied psychologists endorse what they call an 'assessment' approach to these decisions, in which the decision maker intuitively weighs all the information gathered about the person. In contrast, a 'statistical' approach inserts personality scores into a mathematical equation developed from past empirical research. Studies indicate that statistical predictions are almost invariably more accurate than assessment predictions.

3.2 Helping People Make Decisions

Methods for helping people make decisions with personality measures differ from making decisions

about people only in terms of who is making the decisions. Individuals seeking greater satisfaction in personal relationships, for example, may complete a personality questionnaire to increase self-insight, much as they might read a self-help psychology book. Likewise, individuals uncertain about career choice can complete questionnaires that predict which careers would be most satisfying. Traditionally, psychologists interpret and discuss personality scores with clients, but some self-help personality measures are completely self-administered.

3.3 Basic Research: Uncovering Covariation Among Variables

The usefulness of all applied personality methods depends upon the ability of researchers to construct valid personality measures and to ascertain reliable covariation among these measures. This process, called 'construct validation,' is identical with any other type of scientific hypothesis testing (Hogan and Nicholson 1988). In the typical case, construct validation takes the following form. A researcher's theory predicts that individual differences in a particular personality trait (say, conscientiousness) will covary with differences in some L-data (say, job performance). A method is devised to measure the personality trait with O-, S-, or T-data and the life event with L-data. Successful prediction supports both the validity of the measures and the theory that led to the prediction. Predictive failure means either the hypothesis was incorrect, a procedural error occurred (inappropriate research sampling, administration, or scoring), or one or both of the measures lack validity. Progress in personality research occurs when many successful predictions leads to the acceptance of a measure as 'well-validated.' Careful research with well-validated measures always advances knowledge because even predictive failures indicate the need to revise hypotheses.

Because valid measurement is crucial to the entire personality enterprise, a significant amount of personality research is directed at improving measurement methods. Some of this research aims to clarify the dynamics of the measurement process, that is, the psychological processes that occur during observer judgments and self-reports. A second line of research employs computers to administer, score, and interpret personality tests. When computer programs for analyzing personality data are combined with artificial intelligence, 'observers' with artificially constructed personalities will some day make 'observer judgments' of personality worldwide over the Internet.

Personality Structure

Personality structure is the branch of personality psychology that is concerned with quantitative representations of the ways in which persons consistently differ from one another in their characteristic adaptations to social environments (see *Personality and Adaptive Behaviors*). The basic unit of study is the ‘personality trait’ which is considered to be a moderately heritable disposition to behave consistently across different situations. Such traits are thought to

be manifest in the individual differences in thinking, feeling, and behaving reported in responses to personality questionnaires or to lists of trait-descriptive adjectives. Current research in the field of personality structure emphasizes two quite different structural representations of personality traits: the Five Factor Model (FFM) of personality traits and the Interpersonal Circumplex (IPC) model of interpersonal dispositions. These two models originated in different historical contexts, are based on different assumptions concerning the nature of traits, and employ different statistical models for representing dimensions of personality. Nevertheless, the FFM and the IPC models of personality structure may be viewed as complementary rather than competitive, and as being applicable to different but equally important realms of knowledge.

1. Origins of the Five Factor Model of Personality Structure

The idea that variations in human characteristics have an evolutionary origin was suggested at the end of the eighteenth century by Erasmus Darwin (1731–1801) and it later bore fruit in the empirical researches of two of his grandsons, Charles Darwin (1809–82) and Francis Galton (1822–1911). That Galton was uniquely qualified to conduct research on ‘hereditary genius’ is suggested by the accomplishments and eminence of the Darwin family and by the fact that Galton was, by any criteria, a genius himself. Galton coined the term ‘eugenics’ (Greek *eugenes* ‘well-born’) for the field which studied the inheritance of desirable characteristics, especially intelligence. In 1904, Galton endowed a permanent chair in eugenics at University College, London and appointed the mathematician, Karl Pearson (1857–1936) as its first professor. Pearson developed the correlation coefficient to express the relation between the intelligence of parents and the intelligence of their offspring. His colleague, Charles Spearman (1863–1945) developed the method of factor analysis (see *Personality Psychology: Methods*) which, when applied to mental ability data, suggested a general factor of intelligence (‘g’) in addition to more specific factors. Raymond B. Cattell (1905–98), the founder of modern personality structure research, received his doctorate under Spearman and was the first to suggest extending the applications of factor analysis to the study of individual differences in personality characteristics.

Cattell (1967) had a master plan for the study of personality structure, which he and his associates implemented over a period of 65 years: (a) determine the totality of trait-descriptive terms in a given language that denote individual differences in thinking, feeling, and behaving (‘surface traits’); (b) reduce correlated clusters of these surface trait terms by

factor analysis to their underlying determinants ('source traits'); and (c) confirm, by factor analysis and experimentation, the extent to which these source traits, as measured by personality questionnaires, may also be found in different media of observation such as ratings by observers, self-ratings, and behavioral responses to controlled test stimuli. Cattell's master plan set the stage for two distinct, but conceptually related, approaches to the study of personality structure that have only recently converged.

2. Two Traditions of Five Factor Model Research

2.1 The Lexical Tradition

The totality of surface traits in a given language may be defined with reference to the words that are used to mark individual differences in thinking, feeling, and behaving found in an unabridged dictionary of that language. Within the lexical tradition, representative words (typically adjectives) that have been selected from dictionaries are administered in self-report and observer-report format to groups of respondents who indicate the extent to which each word is descriptive of themselves or of someone they know well. Such data are then analyzed by first calculating the extent of co-occurrences (correlations) among words, and then determining the underlying 'structure' of the entire set of words by factor-analytic techniques.

Lewis R. Goldberg (1981) maintained that: (a) the frequency with which an attribute is represented in a language corresponds to the general importance of that attribute in a given culture and (b) the most important dimensions of personality are those 'universal dimensions' that are common to all languages. Goldberg and his colleagues have studied personality trait-descriptors in English and 12 other languages (e.g., German, Italian, and Turkish) and have concluded that there are *five factors* (which they called the 'Big Five') that may be considered universal dimensions of personality surface trait structure (see *Cross-cultural Psychology*). The Big Five dimensions of personality that have been identified in many different language groups are: (a) Extraversion (talkative, assertive, verbal); (b) Agreeableness (kind, cooperative, warm); (c) Conscientiousness (organized, systematic, practical); (d) Neuroticism (anxious, moody, emotional); and (e) Intellect/Openness (intellectual, imaginative, complex).

2.2 The Multivariate-trait Tradition

The second part of Cattell's master plan involved the development of personality questionnaires that would capture the basic dimensions of personality inherent in language. A personality questionnaire consists of items such as 'I like to attend parties and other social

gatherings where I can meet new people' to which the test-taker is required to respond 'true' or 'false'; or more typically, to rate the degree to which the statement is self-descriptive on a scale ranging from 'not at all' to 'highly descriptive.' Most questionnaires are designed to measure many dimensions or variables, and hence are called 'multivariate.' Because responses to questions ('true vs. 'false'; 'descriptive' vs. 'non-descriptive') can be scored with complete reliability, the tests are referred to as 'objective.'

Cattell's suggestion that Spearman's statistical method of factor analysis could be applied to personality data was indeed a fruitful one, but the new field of personality structure also inherited some of the problems that had been associated with the use of factor analysis to determine the number and nature of mental abilities. Foremost among these problems was the issue of determining the *number* of factors 'underlying' the intercorrelations among personality scales. For example, the two most prominent figures in the field of personality structure during the twentieth century, R. B. Cattell in the United States and H. J. Eysenck in England, strongly disagreed about the number of factors that were required for the comprehensive measurement of personality structure. Cattell argued that at least 16 factors were necessary and he included these factors in his Sixteen Personality Factor Questionnaire (16 PF). Eysenck held that there were, at most, the three factors included in the Eysenck Personality Questionnaire (EPQ). A 1953 survey of the literature by psychologists at the Educational Testing Service identified and categorized the approximately 450 factors that had been reported up to that date. By the 1960s, the field of personality structure was being severely criticized, not only for its failure to agree on a common set of factors, but for its failure to demonstrate any substantial 'real world' correlates of such factors. At the same time, however, it was argued that the 'Big Two' dimensions of personality, Extraversion (see *Self-esteem in Adulthood*) and Neuroticism (see *Neuroticism*) were large, ubiquitous, and almost unavoidable dimensions of personality for which substantial and important correlates had been reported (Wiggins 1968). These dimensions had figured prominently not only in the research programs of Cattell and Eysenck, but in many other research contexts as well.

2.3 Reconciliation of the Two Traditions

P. T. Costa, Jr., and R. R. McCrae (1994) developed a personality questionnaire that included scales for the dimensions of Neuroticism and Extraversion suggested by Cattell and Eysenck, as well as a measure of Openness to Experience that was suggested by an analysis of Cattell's questionnaire. Their instrument, the NEO-Personality Inventory (NEO-PI), was later expanded to include the additional dimensions of Agreeableness and Conscientiousness that had been

identified in the lexical work of Goldberg and others. During the 1980s and 1990s, Costa and McCrae conducted an unprecedented number of empirical studies with the NEO-PI that established the utility of this instrument, as well as the comprehensiveness of what came to be known as the Five Factor Model (FFM) of personality structure. In addition to revitalizing the field of personality structure, the work of Costa and McCrae reaffirmed the basic logic of Cattell's master plan which called for an integrative framework for research that included both the lexical and multivariate-trait traditions.

3. Research with the NEO Personality Inventory

The NEO-PI has been an especially useful measure in the 'applied' contexts of personnel selection (Barrick and Mount 1991) and psychiatric diagnosis (Costa and Widiger 1992). In addition, the validity of the NEO-PI as a conceptually-justified measure of personality traits has been demonstrated with reference to the following criteria that would be required of such a measure.

3.1 Heritability and Stability

All five of the NEO-PI dimensions are moderately heritable (see *Behavioral Genetics: Psychological Perspectives*) and remarkably stable over the adult life of an individual. After the age of 30, these traits, as William James put it, appear to be 'set like plaster.' Costa and McCrae (1994) reported retest correlations ranging from 0.6 to 0.8 even after an interval of 30 years.

3.2 Consensual Validation and Cross-cultural Invariance

There are reasons to be skeptical of the 'truthfulness' of individuals' self-reports to personality inventories and for that reason, it is desirable to obtain ratings by knowledgeable observers of the respondent's personality characteristics on the same items (see *Person Perception, Accuracy of*). In many of the empirical studies conducted by Costa, McCrae, and associates, an Observer Form of the NEO-PI was completed by spouses, peers, or other knowledgeable informants. In general, substantial agreement has been obtained between self- and observer-ratings, indicating a satisfactory degree of 'consensual validity.' The NEO-PI has been translated into more than 30 languages, including non-Indo-European languages such as Thai and Shona. The success of these translations in producing the expected five-factor structure in other cultures attests to the cultural generalizability of the Five-Factor Model.

4. Origins of the Interpersonal Circumplex Model

Circular representations of human nature can be traced from ancient astrology to the drawings of Leonardo Da Vinci to the modern interpersonal circumplex tradition, which began with Harry Stack Sullivan. Sullivan defined psychiatry as the study of *interpersonal relations* and considered 'personality' to reside in an individual's patterns of relationships with significant others over time. Timothy Leary (1957) and his associates attempted to operationalize Sullivanian concepts in terms of concrete measurement procedures. Their analysis of clinicians' observations of the things that patients did to each other (and to themselves) in group psychotherapy led to a taxonomy of interpersonal variables that was empirically well captured by a *circular* arrangement of 16 (later 8) variables organized around the two coordinates of dominance (vs. submission) and affiliation (vs. hostility).

4.1 The Structure of Interpersonal Behavior

The Five Factor Model and Interpersonal Circumplex are based on different assumptions about the nature of personality and employ quite different structural models. The tradition that led to the current FFM focused on the *individual* and attempted to provide a comprehensive 'list' of the factors necessary for describing the individual's most important personality traits. The tradition that led to the current IPC focused on *dyadic relationships* and attempted a detailed description of a two-dimensional 'interpersonal space' within which interpersonal actions and reactions could be classified. The IPC tradition assumes that a person's characteristic interpersonal behavior may be expressed as a *combination* of scores on the two bipolar coordinates of Dominance (vs. Submission) and Affiliation (vs. Disaffiliation).

Interpersonal space is interpreted, quite literally, in terms of the geometry of the circle. The two underlying coordinates of this circle are Dominance (90°) vs. Submission (270°) and Affiliation (0°) vs. Disaffiliation (180°). A number of theoretical rationales have been given for the assumption that these coordinates are the 'basic' reference points for understanding interpersonal behavior. For example, it has been suggested that David Bakan's (1966) distinction between agency (being a differentiated individual, striving for mastery and power) and communion (being part of a larger entity, striving for intimacy and union) provides a metatheoretical basis for interpreting Dominance and Affiliation as the basic axes of social life. Within this conceptual framework, Dominance vs. Submission and Affiliation vs. Disaffiliation are the nodal reference points on the IPC and all other behaviors may be interpreted as 'blends' of these two coordinates. For example, Extraversion (45°) is an

equal blend of Dominance and Affiliation; Introversion (225°) is a combination of submissive and disaffiliative tendencies.

4.2 The Nature of Interpersonal Space

Unlike the competing inventories of personality structure found within the multivariate-trait tradition (e.g., Cattell, Eysenck, Costa, and McCrae), different IPC measures share the same structure, but differ in their domains of application. For example, IPC models of personality and emotions have coexisted comfortably for many years and are likely to continue to do so (Plutchik and Conte 1997). Four contemporary IPC measures have quite different areas of application: The Interpersonal Adjective Scales provide a measure of relatively normal interpersonal *traits* or dispositions. The Inventory of Interpersonal Problems measures *problems* of living as perceived by respondents or others. The Impact Message Inventory measures the *covert reactions* of respondents to different target persons corresponding to different locations on the IPC. The Supportive Actions Scale measures tendencies to provide various kinds of *social support* to others in need of assistance. It is clear from the approximately 1,000 references that appeared in Donald Kiesler's (1996) survey of the IPC literature that both the utility and generalizability of the IPC structure are well established.

5. Current Status

Examination of the relevant literature of the past decade reveals that the two major models of personality structure today are the Five-Factor Model or 'Big Five' and the Interpersonal Circumplex model. An early rapprochement between these two models occurred when proponents of each of the models agreed that the Extraversion and Agreeableness dimensions of the FFM were rotational variants of the interpersonal dimensions of Dominance and Affiliation and that a full description of personality structure cannot ignore the additional dimensions of Conscientiousness, Neuroticism, and Openness/Intellect. It has also become increasingly apparent that the FFM, which had been characterized by some as an 'atheoretical' model, lends itself to interpretations from a variety of different theoretical perspectives (Wiggins 1996).

Personality Theories

Within psychology, personality refers to the individual's distinctive and enduring characteristics, including stable patterns of thoughts, feelings, emotions, and behavioral tendencies. No other area of psychology covers as much territory as the field of personality does; it is at the intersection of the study of human development, abnormality and deviance, temperament, emotions and thought, learning, social relations, and even the biological foundations of human behavior. Although the traditional focus is on stable individual differences in basic tendencies or dispositions (e.g., extraversion, conscientiousness), recent approaches also emphasize the psychological processes (such as learning, motivation, emotion, and thinking) that underlie them. Increasing attention is also given to the possible biological-genetic roots of these tendencies and processes, and their interactions with social-environmental influences.

Personality theorists try to answer such questions as: How stable and enduring are particular psychological qualities? What is the role of inheritance in the expression of personality, and what is acquired through experience with the environment? Does what

we do and think and feel characteristically depend mostly on the individual or on the situation? How do different types of people interact with different types of situations? Historically, there have been five main approaches to personality that address these questions: the psychodynamic, the behavioral, the phenomenological, the trait and biological, and the social cognitive. All are concerned with uncovering basic, general principles that can account for the wide range of behavior that people are capable of engaging in, and each proposes different units for conceptualizing and studying people. Each approach is considered in turn.

1. Psychodynamic Approaches

The psychodynamic approach to personality was founded by the Viennese physician Sigmund Freud; (see *Freud, Sigmund (1856–1939)*). Rejecting the earlier belief that people's behavior is under their conscious and rational control, Freud believed that behavior is psychologically determined by underlying unconscious causes and motives. Freud saw patients who displayed strange symptoms that had no discernible physical cause, such as a young woman who appeared to be blind although tests of her vision showed that her eyes and visual system were undamaged. To explain such puzzling cases, Freud proposed an 'anatomy' of the mind consisting of three institutions or agencies of mental operation—the id, the ego, and the superego. The id—the primary, instinctual core—obeys the 'pleasure principle,' seeking immediate gratification of basic biological sexual and aggressive impulses, regardless of reality considerations. The superego, on the other hand, represents the moral standards of a person's society, obtained through the internalization of parental values, rules, and characteristics in the course of socialization. The ego mediates between the instinctual demands of the id and the outer world of reality, localizing the appropriate objects for gratification in the environment so that the impulses of the id can be satisfied. It operates by means of logical thinking and rational planning. Its tasks include: (a) the control of unacceptable impulses or desires from the id; (b) the avoidance of pain produced by internal conflict in the efforts to control and master those unacceptable impulses; and (c) the attainment of a harmonious integration among the needs of both the id and the superego.

According to Freud ([1915] 1957), the id, the ego, and the superego are always in dynamic conflict (thus the term psychodynamics). Freud believed that in this conflict, a person's basic impulses persist and press for discharge, but the people or 'objects' at which they are directed, and the manner in which they are expressed, are transformed and disguised unconsciously to make them more acceptable and to reduce conflict and

anxiety. When the young child becomes anxious about his or her own impulses (e.g., because of fear that they will lead to parental punishment), attempts are made to repress them or otherwise disguise and redirect them. The main defense mechanism that Freud proposed—repression—massively inhibits threatening impulses or events, making them unconscious. In projection, one's unacceptable impulses or aspects are attributed to other people.

Modern psychodynamic theories tend to place much less emphasis on biological drives and highlight the individual's social circumstances and relationships with significant others. Attachment theorists, for example, emphasize the quality and varieties of early mother-child attachment relations and their consequences in the course of development (Ainsworth and Bowlby 1991). Based on experiences in this relationship, the child develops internal working models (mental representations) of others, of the self, and of relationships, which guide subsequent experience and behavior. Children who have positive, gratifying experiences with significant others tend to develop internal working models of others as responsive and giving, and of themselves as worthy of attention; those who have had painful or unsatisfying experiences are likely to develop internal models that reflect those troubled relationships. Early attachment styles may enduringly influence relationships throughout life, including the way one parents one's own children (Hazan and Shaver 1987; see *Attachment Theory: Psychological*; Bowlby, John (1907–90)).

Many of the ideas introduced by the psychodynamic approach, notably that much mental activity occurs outside of mental awareness, also are being reconceptualized in light of current theory and findings on how thought and memory work. For example, when cognitive (mental) representations of significant others are activated by a newly encountered person, the feelings and attributes associated with this representation may be applied to that new person in making inferences about him or her (Andersen and Berk 1998). This is consistent with Freud's concept of transference, said to occur when the patient responds to the therapist as if he or she were the patient's father, mother, or some other childhood figure. This modern approach, however, views transference in information-processing terms rather than as a reflection of the psychosexual impulses and conflicts hypothesized in classical psychodynamic theory (Westen 1998; see *Mental Representation of Persons, Psychology of*).

2. Behavioral Approaches

Although many psychologists were intrigued by the insights of Freud and his followers, they were primarily dedicated to developing a more scientific, rigorous approach to personality that would be objectively testable, preferably by laboratory tech-

niques. One of the pioneers in the behavioral approach, the US psychologist B. F. Skinner (1904–90), criticized many motivational concepts as being no more than labels, and even fictions, that were unhelpful for explaining what people actually do. Skinner and other behaviorally oriented psychologists analyzed problematic behaviors (e.g., aggressiveness, bizarre speech patterns, smoking, fear responses) in terms of the observable events and conditions that seem to vary with them. They then tried to discover the external events that strengthened their future likelihood and that maintained or changed the behavior of concern. Behavioral approaches have led to innovations for therapy by attempting to modify problematic behavior not through insight, awareness, or the uncovering of unconscious motivations, but rather by addressing the behavior itself and modifying it directly. Such behavior therapies emphasize the individual's current maladaptive behaviors (rather than their historical origins) and assume that they can be understood and changed by learning principles that deal with the acquisition and extinction of behavior patterns.

Although the systematic rigor of behavioral approaches was widely appreciated, the relevance of the approach for understanding the complex lives of people under the often unpredictable social conditions of life remained in question. Thus, a number of theorists began to make learning and behavior theories more 'social,' not limiting themselves to simple reinforcement principles and increasingly relying on mental or 'cognitive' processes in their account of the development of complex social behavior. In Albert Bandura's (1986) social learning approach, for example, personality is seen as the outcome of social learning processes through which distinctive beliefs, self-efficacy expectations, as well as personal standards that guide characteristic behavior patterns, are acquired. He emphasized that much social learning, from table manners and interpersonal relations to working habits to coping patterns, occurs through observation of the behavior of social models without any direct rewards or reinforcement administered to the learner (see *Social Learning, Cognition, and Personality Development*).

In another direction, the assumption that the 'laws' of conditioning are universal and apply broadly has been challenged by convincing evidence that organisms (including humans) seem biologically prepared to learn some associations or pairings more readily than others. Prewired dispositions in the brain seem to make humans distinctively prepared to learn diverse high-level mental activities, from language acquisition to mathematical skills to space perception (Pinker 1997). In yet another direction, technological advances in brain imaging now allow researchers to use methods like Magnetic Resonance Imaging (MRI) to observe areas within the brain that become activated in the course of mental activity, such as the emotional centers that may be especially important bases for individual

differences (Ledoux 1996). Advances in technology have therefore made it possible to objectively study mental events, such as emotions, memories, and attention, going far beyond the early behaviorism that confined itself to overt behavior.

3. Phenomenological Approaches

In the middle of the twentieth century, phenomenological approaches arose, in part, as a humanistic protest against the earlier psychodynamic and behavioristic views. Phenomenologically oriented theorists argued that personality is not merely passively molded by internal motivational or external situational forces that 'shape' what the person becomes. Instead, people are active agents in the world and have a measure of control over their environment and their own lives. In this view, people are considered capable of knowing themselves and of being their own best experts. Self-knowledge and self-awareness become the route to discovering one's personality and genuine self.

Phenomenological approaches to personality (sometimes called self theories, construct theories, and humanistic theories), tend to reject many of the motivational concepts of psychodynamic theories and most of the environmental determinism of behavioral theories. Instead, their focus is on the development of an active 'self': People develop self-concepts and goals that guide their choices and their life course. Understanding personality, as well as the person's goals and choices, requires attention to how the individual characteristically perceives, thinks, interprets, and experiences or even 'constructs' the personal world.

George Kelly's (1905–67) theory of personal constructs, for example, emphasized people's subjective perceptions as the determinants of their behavior. Kelly believed that, just like scientists, people generate constructs and hypotheses both about themselves and about how the world works; they use these constructs to anticipate, understand, and control events in their lives. Therefore to understand people, one has to understand their constructs, or personal theories. Problems develop when the constructs people generate don't work well for them, when they are 'bad scientists' and fail to 'test' their constructs or hypotheses against the realities of the environment, or when they see themselves as helpless victims of their own personalities or life situations. Kelly's principle of 'constructive alternativism' held that all events in the world, including one's own behavior and characteristics, can be construed in multiple, alternative ways. While it is not always possible to change these events, one can always construe them differently, thus influencing how one is affected by them and how one reacts to them.

Carl Rogers (1902–87), another pioneer of the phenomenological approach, proposed two systems:

the organism and the self (or self-concept). The organism is the locus of all experience, which includes everything potentially available for awareness. The self is that portion of the perceptual field that is composed of perceptions of characteristics of the 'I' or the 'me.' It develops from experiences and interactions with the environment, and also shows a tendency towards actualization. Rogers maintained that the central force in the human organism is the tendency to actualize itself—to move constructively in the direction of fulfillment and enhancement. The self may be in opposition or in harmony with the organism. When the self is in opposition or incongruence with the experiences of the organism (e.g., when the self tries to be what others want it to be instead of what it really is), the person may become anxious, defensive, and rigid. However, when the self is open and accepting of all of the organism's experiences without threat or anxiety, the person is genuinely psychologically adjusted, for the self and the organism are one.

In contemporary work, the 'self' is seen as multifaceted and dynamic, consisting of multiple self-concepts that encode different aspects of the person (e.g., self as lover, self as father, the 'ideal' self, the 'actual' self) and become differentially salient depending on context (Markus and Nurius 1986). According to Higgins (1987) for example, a perceived discrepancy between the mental representation of the person one would ideally like to be (the ideal self) and the representation of who one actually is (the actual self) makes one more vulnerable to feelings of dejection, such as disappointment or dissatisfaction. In contrast, a discrepancy between one's representation of who one ought to be (the ought self) and the actual self can lead to feelings of agitation such as fear and worry. Motivation for behavior change arises from the conflicts each individual feels among his or her various representations of the self. For instance, upon receiving a low grade on an exam, an undergraduate may subsequently study very hard to relieve the guilt of not living up to what she herself perceives to be her responsibility as an exemplary student. Alternatively, she may re-evaluate her negative interpretation of past events, thinking about all of the good grades she has got in other classes and the myriad of other activities she is involved in (see *Personality and Conceptions of the Self*).

4. Trait and Biological Approaches

In everyday life, people readily characterize each other in terms of personality characteristics: he or she is friendly, assertive, submissive, conscientious, and so on. The essence of the trait approach, whose fundamental premises date back to the ancient Greeks, is the assumption that behavior is primarily determined by a number of stable, generalized personality traits that express themselves in many contexts. Guided by

this assumption, advocates of this approach try to identify and measure individuals' traits and to discover the most fundamental traits on which people can be compared.

A principal focus of research on traits is on measurement—that is, the development of quantitative ways of finding and describing important stable individual differences. Traits are inferred from questionnaires, ratings, and other reports about the person's dispositions. Usually, the person's self-reports (or someone else's reports about the person) are taken as direct signs of the relevant traits. For example, the more one rates oneself as aggressive, the more one is assumed to have an aggressive disposition. The trait approach recognizes that behavior can vary depending on the situation but has focused on individual differences in the overall response tendency averaged across many situations.

Some consensus has grown among many researchers to focus on five large factors or dimensions of personality that have emerged from statistical analyses of traits. These factors, often referred to as the 'Big Five,' comprise openness to new experience, conscientiousness, extraversion (or outgoingness), agreeableness, and neuroticism. Considerable stability has been demonstrated on trait ratings and questionnaires related to the Big Five, particularly during the adult years (McCrae and Costa 1990; see *Extraversion; Neuroticism*).

In a different direction, the British psychologist Hans Eysenck (1916–97) and his associates have led the way in connecting psychological dispositions to their biological foundations. According to Eysenck, introverts need only a small amount of stimulation to overstimulate their central nervous system (CNS) which then leads them to become withdrawn in their behavior. In extraverts, by contrast, the CNS is not easily stimulated, leading them to seek activities that will increase stimulation levels, for example, by socializing more actively and by seeking activities such as parties. In support of his theory, Eysenck (1971) found that extraverts reported earlier, more frequent, and more varied sexual experiences. In another study, introverts showed greater changes in their brain wave activity in response to low frequency tones (Stelmack and Michaud-Achiron 1985), indicating their lower threshold for stimulation to the CNS.

4.1 Genetic Roots of Personality

The rapidly developing field of behavioral genetics studies the role of inheritance in personality, both in terms of dimensional traits (such as extraversion–introversion) and temperaments (such as general levels of emotionality, sociability, and activity; see *Temperament and Human Development*). Behavioral genetics most often uses the 'twin method' to assess genetic influence, comparing the degree of similarity on trait measures obtained for genetically identical (mono-

zygotic) twins as opposed to twins that are fraternal (dizygotic) and are only 50 percent similar genetically. To the degree that genetic factors affect a trait, it follows that identical twins must be more similar than fraternal twins with regard to that trait. Estimates of genetic influence vary across studies and measurement strategies. For example, they tend to be higher for self-reports of personality than for observational studies (Miles and Carey 1997). Nevertheless, the general conclusion that identical twins are more similar than fraternal twins has received considerable support, and indicates an important role of heritability in personality (Plomin et al. 1997).

Even highly heritable dispositions, however, can be constrained and limited in their full expression, as when a person's growth and ultimate height are affected by nutrition, disease, or development. Environmental influences also can change the hard wiring of the brain—the neuronal structures themselves—and thus produce stable changes within the person at the organic level. For example, stress can shrink the size of the hippocampus, a brain structure basic for higher order mental functions (Sapolsky 1996). Thus, although the social environment cannot affect the structure of DNA (barring biochemical or radiation exposure), it can influence their expression, the brain, and the person's personality (see *Behavioral Genetics: Psychological Perspectives*; *Stress: Psychological Perspectives*).

Unquestionably, one's genetic endowment has extensive influence on one's life and personality development. Just as noteworthy, however, the same findings also point to the importance of experiences and the environment for personality (Plomin et al. 1997). The expressions of genetic influences and the situations and events the person experiences are in continuous interaction, and it may be this interplay that is most important in personality development.

5. Social Cognitive Approaches

In the 1960s, a 'cognitive revolution' took place in psychology, as attention turned from behavior to the person's mental (cognitive) processes and structures. Although behavioral approaches had asserted that stimuli control behavior, evidence accumulated to suggest that the perceivers' mental representations and cognitive transformations of stimuli can determine and even reverse their impact. Such transformations were illustrated in research on the determinants of people's ability to forgo gratifying their immediate impulses for the sake of more highly desired but temporally distant goals. This kind of 'willpower' has been studied extensively in the delay of gratification paradigm, in which preschoolers are faced with the dilemma of being able to have a small, less desired reward now (e.g., one little pretzel or marshmallow) or having to wait instead for a larger, more desired

reward (e.g., two little pretzels or two marshmallows). The number of seconds that preschoolers are able to delay predicts a variety of positive developmental outcomes, including their SAT scores and their social competence in adolescence (Mischel et al. 1989; see *Self-regulation in Childhood*; *Self-regulation in Adulthood*). The duration of delay time itself depends importantly on how the children represent rewards mentally and selectively attend to different features of the situation. For example, if the young child focuses cognitively on the consummatory qualities of the reward objects, such as the pretzel's salty, crunchy taste, he or she tends to be able to wait only a short time. By thinking about the stick pretzels as little logs or about the marshmallows as puffy clouds, however, the child may be able to wait much longer for the reward. These results indicate that what is in the children's heads—not what is physically in front of them—determines their ability to delay.

Concurrent with the cognitive revolution, questions arose about cross-situational traits and psychodynamics as basic units of personality. Walter Mischel (1968) in particular showed that what people do characteristically depends importantly on the situation and context. For example, the person who seems conscientious about work may show a very different pattern with family. These findings indicated that broad trait scores and projective psychodynamic methods do not accurately predict what a given person will do in different kinds of situations and fail to explain the seeming inconsistency or variability that was observed within individuals across those situations.

The social cognitive approach to personality emerged in the 1960s and 1970s as an attempt to understand both the stable ways in which the person cognitively processes social information and the ways in which the person's behavior varies with regard to the situation. In this approach, the basic 'units' of personality are conceptualized as a set of five relatively stable person variables (Mischel and Shoda 1995): the individual's encodings or construals (of self, other people, situations); expectancies and beliefs (about outcomes and one's own self-efficacy); subjective goals and values; competencies (for the construction and generation of social behavior) and self-regulatory strategies and plans in the pursuit of goals; and their affects (feelings, emotions, and affective responses). Furthermore, clues about the person's underlying qualities may be seen in when and where a type of behavior is manifested, not only in its overall frequency. If so, the patterns of situation-behavior relationships shown by a person might be a possible key to individuality and personality coherence, rather than a source of error to be eliminated systematically (see *Interactionism and Personality*).

Evidence for the existence and meaningfulness of the stable situation-behavior relations predicted by the social cognitive approach came from an extensive

observational study conducted in a residential summer camp setting for children (Shoda et al. 1994). In this study, children's behavior was recorded specifically in relation to five camp-relevant situations (e.g., being teased, threatened, or provoked by peers; being praised by an adult). The children's social behavior was observed on selected dimensions (e.g., aggression, withdrawal, friendly behavior) as it occurred in relation to each of the interpersonal situations. The individuals' situation-behavior, 'if ... then ...' personality 'signatures' (e.g., if situation X, then they do A, but if situation Y, then they do B) were found to be both distinctive and stable. For example, one child was consistently more verbally aggressive than others when warned by an adult, but showed less aggression than others on average when approached positively by a peer. In contrast, another child was most verbally aggressive when approached positively by peers, but not particularly aggressive when warned by an adult.

To account for such findings, a cognitive-affective personality system (CAPS) theory has been proposed (Mischel and Shoda 1995). In this theory, the individual is characterized not only by the particular subset of goals, ways of encoding the world, and self-regulatory competencies that may be potentially accessible to him or her, but also by the distinctive and stable organization of relationships among the person variables available in the personality system—i.e., the person's distinctive 'network.' When a person encounters a particular situation, the CAPS network is sensitive to particular features of situations, which become encoded and activate situation-relevant cognitions and affects (thoughts and feelings) within the system. These units, in turn, make other cognitions and affects accessible while inhibiting others. The organization of relations within the person's network remains relatively stable and invariant across situations. However, as the individual moves across situations that contain different psychological features, different mediating units and their characteristic interrelationships become activated in relation to these psychological conditions.

Thus the person's unique 'network'—which is distinctive both in the types of mediating units available within the system as well as in the relationships among these units—guides and constrains the activation of the specific cognitions, affects, and potential behaviors when an individual processes situational features. It constitutes the basic structure of personality and reflects and underlies the individual's uniqueness. When the *ifs* posed by the situation change, so do the *thens* generated by the personality system, but the relationship between them is stable. This type of system is intrinsically interactionist, and has been shown to generate both overall mean differences in a given behavior as well as the specific *if ... then ...* profiles that are a person's behavioral 'signature.'

To illustrate such a system in action, suppose a person is especially sensitive to rejection and is

disposed to expect it, to look for it, and to react intensely to it (Downey and Feldman 1996). Such 'rejection sensitive' people may see even innocent or ambiguous behavior from a significant other as intentional rejection, triggering such thoughts as 'she doesn't love me,' which activate further thoughts and feelings of rejection and potential betrayal and abandonment. In turn, the person's scripts for coercive or controlling behaviors may become activated, leading to angry or hostile and even abusive reactions. Over time such hostility is likely to lead to actual rejection even when there was none before, further strengthening the cycle that characterizes this personality type.

Thus, the defining *if ... then ...* profile of rejection sensitivity—its behavioral signature—may include both being more prone than others to anger, disapproval, and coerciveness in certain types of situations in intimate relationships, as well as being more supportive, caring, and romantic than most people in other situations (e.g., in initial encounters with potential partners who are not yet committed to them). This example illustrates how the personality system remains stable, although the surface behaviors it generates change in relation to the situation. As in a musical piece, the notes played at any moment change, but they do so in an organized pattern that reflects the structure of the composition.

6. Future Directions: Toward a Cumulative Science of Personality

Historically, the field of personality has been characterized by many alternative approaches and conceptions of personality which competed against each other. Different approaches and theorists claimed to offer a comprehensive, unitary view of personality, to the exclusion of alternative viewpoints or approaches. However, the different approaches at least in part asked different questions, usually dealing only with selected aspects of the diverse phenomena subsumed under the construct of personality.

Personality psychologists are increasingly recognizing the importance of multiple approaches to understanding the person and many are trying to find ways to integrate them within a broader theoretical framework. Current psychodynamic approaches are beginning to incorporate insights from research on memory to test the fundamental tenets of psychodynamic theory. Similarly, some behavioral approaches are integrating findings on social learning and cognitive processes, aided by current technology to assess interactions between biological variables and learning. The phenomenological approach, with its emphasis on the person's subjective internal reality, continues to inform work on self-conceptions and how these influence the individual's choices and life course. Trait approaches are beginning to specify the boundary conditions within which traits will be selectively

activated and visible in behavior. Finally, cognitive-social approaches are incorporating the contributions of cognitive science and social psychology into the same framework used to understand the individual's characteristic cognitive-affective processes and dynamics. If these trends continue, personality psychology may be evolving into a more unified field that addresses the distinctive characteristics that people have and the psychological processes that underlie them, conceptualized within one overarching theoretical framework.

W. Mischel and R. Mendoza-Denton

Personality Theory and Psychopathology

The idea that enduring personality traits are closely related to various disease states or behavioral disorders can be traced back to initial speculation by the early Greeks. Hippocrates believed that all disease stemmed from imbalances in four bodily humors: yellow bile, black bile, blood, and phlegm. While Hippocrates' early ideas bear a rudimentary resemblance to some recent approaches to personality, most contemporary theories of the relationship between personality and psychopathology are considerably more complex, and sensitive to both endogenous and environmental variables. Before the personality–psychopathology relationship can be understood clearly, the concept of personality must be defined.

1. The Concept of Personality

The word personality is derived from the Greek *persona*, which referred to masks used in the early theater. Over time, the term has come to refer not only

to the exterior presentation of an individual, but the integrated internal systems which allow individuals to adapt to their environment. For example, Allport (1937) defined personality as 'the dynamic organization within the individual of those psychophysical systems that determine his unique adjustments to his environment.' This definition highlights the idea that personality reflects both psychological and biological processes that are used in coping with the everyday world. These points are made more clearly by Millon (1996, p. 4), who defines personality as 'a complex pattern of deeply embedded psychological characteristics that are largely nonconscious and not easily altered, expressing themselves automatically in almost every facet of functioning. Intrinsic and pervasive, these traits emerge from a completed matrix of biological dispositions and experiential learnings and ultimately comprise the individuals distinctive pattern of perceiving, feeling, thinking, coping, and behaving.'

Another important characteristic of personality is that it pertains to long-standing patterns of behavior which are relatively stable over time and are typically referred to as traits. The American Psychiatric Association has defined personality in the *Diagnostic and Statistical Manual of Mental Disorders* (4th edn.) as 'enduring patterns of perceiving, relating to, and thinking about the environment and oneself.' Taken together, the many definitions of personality which have emerged over the years highlight several consistent features: the integration of biological and psychological systems, which results in trait-like behavioral stability and function to promote environmental adaptation.

2. Conceptual Debates Related to Personality

Numerous conceptual debates have characterized the evolution of the study of personality. Pervin (1990) outlines several of these issues: 'Is personality primarily governed by internal factors of the person or environmental effects?'; 'Is personality determined primarily by nature or nurture?'; 'Is personality influenced by past experiences, present factors, or future expectations?'; and 'To what degree is personality modifiable?'

While each of these topics is significant in and of itself, this article will highlight several other key issues regarding the nature of personality which have generated considerable discussion.

3. Trait-like Stability vs. Situational Determinism

As noted previously, personality has historically referred to trait-like behavioral patterns which are stable across situations and time. However, a series of empirical studies in the 1920s and 1930s raised serious

doubts about the trait-like stability of behavior and highlighted the significance of situational factors in determining variability in behavior. Classic studies by Columbia University Teachers College (1928) suggested that children's level of honesty did not follow a trait-like pattern of predictability, but was significantly influenced by the child's immediate environmental situation. Furthermore, numerous other studies emerged suggesting that specific behaviors measured across situations and time were quite variable, further calling into question the idea of trait like stability of behavior (Mischel 1968). Consequently, this era was characterized by a polemic atmosphere in which person vs. situation debates were common.

Ultimately, this criticism of trait constructs was followed by a period of greater integration of situational and trait theories of personality. For example, work by Epstein highlighted that personality traits may not be accurate predictors of specific individual acts, but may be excellent predictors of aggregated behavior across time and situations (Epstein 1979, Epstein and O'Brien 1985). In other words, traits may be good predictors of a person's behavior 'over the long haul.' Furthermore, theories emphasizing person-situation interactionism evolved and brought into greater focus the ways in which personality traits may interact with particular situational variables. The interactionist solution to the person-situation debate was to consider which personality and situational factors interact to produce consistent behaviors vs. those which interact to produce variable behavior (Ekehammer 1974). Behavior within this approach is considered to flow from transactions between a person and the environment, each of which influences the other.

4. Should Disturbances in Personality be Conceptualized as Categories or Dimensions?

Personality researchers frequently debate about whether personality can best be understood in categorical or dimensional terms. That is, is it more useful to determine what 'type' of personality an individual displays rather than what profile of various personality 'traits' best describes the individual? This becomes particularly significant for the study of disorders of personality, given that the primary classification schemes for psychiatric disorders (e.g., *Diagnostic and Statistical Manual of Mental Disorders*, *International Classification of Diseases*) rely on categorical models (see *Syndromal Diagnosis vs. Dimensional Assessment*, *Clinical Psychology* of). Categorical models parallel traditional, medical disease-based practices in which a person is considered either to have a given disease entity or not. Such an approach has a long history in psychiatry and psychology and offers several advantages: (a) clinicians are generally familiar with

the descriptive and clinical terminology and can apply it easily; (b) predictions can be made about a person based on the description of the category; for example, if a person is categorized as sociopathic, we may assume that rule violation or criminal activity is likely; (c) personality types have clear and vivid descriptions which facilitate communication; (d) a disease based approach is appropriate to the extent that personality disturbances are discrete and homogeneous diagnostic entities with minimal overlap between categories.

Unfortunately, the empirical literature has not supported this idea. People generally do not have a particular personality type that can be easily categorized. Rather, personality appears to be better described as an amalgam of traits, and most empirical studies suggest that personality is best conceptualized in such terms. Categorical models of personality have also been criticized because different measures of the same personality category show relatively low concordance or agreement (i.e., poor convergent validity) and also individuals who meet diagnostic criteria for a given personality type often meet criteria for several other types (i.e., poor discriminant validity). Indeed, if personality could be best understood in terms of unique and nonoverlapping categories, such problems with construct validity would not be so prominent. Furthermore, setting the minimum threshold for determining the presence of a personality disorder is a fairly arbitrary procedure and confusion regarding normality vs. abnormality is common. Finally, many personality disorder categories have not shown substantial stability over time, which would be anticipated with a true trait oriented personality disorder.

In contrast, the dimensional personality trait perspective has received considerable support in empirical studies. For example, when individuals with personality disorders are compared with individuals with normal personality, the distribution of personality scores does not show an 'either-or' pattern, suggesting that personality disordered individuals differ from normals only in the *magnitude* of certain key personality traits. Furthermore, a large number of factor analytic studies of personality traits in both normal samples and personality disordered samples yield the same basic factor structure for each population, most often implying that four or five broad personality traits, or factors, may account for variations in both normal and disordered personality. These five factors are frequently referred to as the Five Factor Model (FFM) and they are traditionally labeled in the following manner: Factor 1, surgency or extroversion; Factor 2, agreeableness; Factor 3, conscientiousness; Factor 4, emotional stability or neuroticism; and Factor 5, culture or openness to experience.

From a clinical perspective, the lack of empirical support for categorical distinctions between normal and abnormal personality and different personality types has led some researchers to suggest that personality disorders do not fit the medical model, and

consequently personality 'diagnoses' should not be made. Rather, personality should be 'assessed' along core dimensions, such as the FFM or other clinical dimensions, (e.g., Minnesota Multiphasic Personality Inventory, see Helmes and Reddon (1993) for a review). Livesley et al. (1994) suggest that the simple presence of a personality disorder be determined on the basis of a behavioral pattern that results in personal or interpersonal *dysfunction*, but is then assessed, or described, on the basis of a dimensional system (e.g., FFM). Such an approach acknowledges that certain personality styles indeed cause distress (i.e., disorder), but retains the comprehensive assessment afforded by the dimensional approach. Whether or not such a system will ever be employed in psychiatric or psychological practice is likely to be determined more by political than by scientific forces.

5. *Relationship Between Personality and Psychopathology*

The idea that personality displays an important relationship to various forms of psychopathology has a long-standing history in psychopathology research. Conceptual understandings of the nature of this relationship have varied and generally represent one of several perspectives (Klein et al. 1993, Lyons et al. 1997, see Fig. 1). First, the *predispositional hypothesis* implies that personality variables precede and increase the risk of developing psychopathology. Also, personality and psychopathology are considered to be independent entities in terms of underlying causes or pathophysiology. An example of this perspective can be seen in early speculation that particular personality traits such as compliance, perfectionism, and dependence increase the risk of developing anorexia nervosa. Similarly, one may speculate that in some people, dependency may precede and increase the chances of developing depression. A second perspective, frequently called the *complication* or *scar hypothesis*, implies the opposite relationship between personality and psychopathology. From this view, psychopathology precedes and influences the development of particular personality traits which are considered the residue of the more active psychopathological syndrome. For example, research suggests that personality variables such as interpersonal dependence or obsessionality may increase after the onset of a major psychiatric syndrome such as depression, but then decrease as the syndrome resolves. The 'personality trait' may not be a true trait, but instead a complication of the depression.

A third perspective posits that both personality and psychopathology arise from the same underlying causal process. From such a *spectrum* or *common cause hypothesis*, a third variable is thought to increase the risk of both entities. From a spectrum perspective,

Figure 1

Models of relationship of personality and psychopathological disorders; S_1 – S_5 = symptoms

personality and psychopathology are considered to be quantitative variations of the same underlying process. For example, it could be hypothesized that schizotypal personality traits and schizophrenia each are ‘caused,’ in part, by a particular genetic pattern. Here, schizotypal personality is not thought to cause, or be caused, by schizophrenia. Rather, it reflects variations of the same fundamental disturbance. This ‘spectrum disorder’ may fluctuate from periods of schizotypal personality to more active schizophrenic episodes. Common cause models are similar to spectrum approaches in specifying a common causal variable, but differ because they suggest that personality traits and specific forms of psychopathology are independent entities and not quantitative variations of one particular disorder or psychopathology. For example, obsessive personality traits and certain forms of depression may be posited to be independent entities which both arise from the same early experiences in a family, but they would not be considered variations of the same disorder. Finally, the *pathoplasty hypothesis* refers to the effect that personality may have on the clinical presentation and course of a particular form of psychopathology. This model does not stipulate any specific causal significance to personality, but simply

implies that variations in personality will affect the psychopathology *after* it emerges. For example, an individual with high degrees of the personality trait of extroversion may behave differently when depressed than an individual with very low degrees of extroversion (i.e., introversion). Here personality ‘colors’ the way the disorder is manifest.

Unfortunately, there is a general lack of empirical data to clarify which of these models best characterizes the complex relationship between various forms of psychopathology and a myriad of personality traits. However, it is likely that specific personality traits will show different types of relationships to different forms of psychopathology and furthermore that a given personality trait may relate to psychopathology in a variety of ways. For example, in the study of neuroticism and depression there is evidence to suggest that neuroticism predisposes an individual to develop depression (predisposition hypothesis), predicts the course of depression (pathoplasty hypothesis), and may be exacerbated by the presence of depression (complication hypothesis). Clearly, the study of the relationship between personality and psychopathology is in its infancy and additional empirical studies are needed.

6. Methodological Considerations

Disentangling the relationship between specific personality traits and various forms of psychopathology will require complex research designs and statistical procedures. Clearly, longitudinal studies of individuals will be necessary to examine which facets of personality increase the risk of which disorders. Such research will also clarify which personality dimensions will reflect complications of specific psychopathologies. Additionally, family history studies and behavior genetic designs employing twin studies or adoption paradigms may help to determine more precisely how various forms of personality and psychopathology are transmitted in families and the extent to which they represent variations of the same process.

7. Summary

The study of personality has revealed that in spite of the power of environmental situations to determine behavior, people tend to be relatively consistent across time and situations in terms of their general patterns of behavior. Furthermore, it seems that people tend to differ along a few primary personality dimensions, or factors, which underlie the concept of personality. While personality traits may increase the risk of developing certain disorders or illnesses, the experience of an illness or disorder may also modify personality. Furthermore, people's personality styles will influence the way in which their disorders develop, change over time, and also respond to treatment. Powerful scientific studies which follow individuals over time will ultimately help us to clarify how personality increases the risk of disorder and furthermore how disorder may modify personality.

Person-centered Psychotherapy

Client-centered therapy is an approach to psychotherapy based on trust in the self-directive capacities of the individual. In this respect, it contrasts with other therapeutic orientations where the therapist characteristically acts as an expert.

1. Historical Overview

Psychologist Carl R. Rogers first described this new approach to psychotherapy in a talk in 1940, not realizing the impact it was going to have. This was followed by a full-length book on psychotherapy containing a clearly stated theory of therapy together with a verbatim account of an eight-interview case. This made up approximately two-fifths of the book and was a pioneering method of case presentation at the time.

As client-centered theory and practice developed in the 1940s and 1950s at Ohio State University and the University of Chicago, a far-reaching body of research on a new hypothesis grew up: that if the therapist offered, and the client experienced, a particular kind of relationship characterized by genuineness, unconditional positive regard, and empathy, a self-directed process of growth would follow. Moving to the University of Wisconsin from 1957 to 1963, Rogers and his associates undertook a major research project which tested the client-centered hypothesis with schizophrenic patients. In 1964, he moved to La Jolla, California, using the approach in the United States and abroad, in small and large groups, school systems, workshops, and conflict resolution. The broader application of the principles of client-centered therapy

became known as the person-centered approach. Rogers died in February 1987. The movement he fathered but did not wish to dominate is carried on by a diverse and dedicated international community.

2. Basic Therapeutic Concepts

The following are the fundamental concepts of person-centered psychotherapy:

(a) An actualizing tendency which is present in every living organism, expressed in human beings as movement toward the realization of an individual's full potential.

(b) A formative tendency of movement toward greater order, complexity, and inter-relatedness that can be observed in stars, crystals, and microorganisms, as well as human beings.

(c) Trust that individuals and groups can set their own goals and monitor their progress toward these goals. Individuals are seen as capable of choosing their therapists and deciding on the frequency and length of therapy. Groups are trusted to develop processes that are right for them and to resolve conflicts within the group.

(d) Trust in the therapist's inner, intuitive self.

(e) The therapist-offered conditions of congruence, unconditional positive regard, and empathy:

(i) Congruence has to do with the correspondence between the thoughts and behavior of the therapist, who is genuine and does not put up a professional front.

(ii) Unconditional positive regard, also identified as 'caring,' 'prizing,' and 'nonpossessive warmth,' is not dependent on specific attributes or behaviors of the client.

(iii) Empathy reflects an attitude of profound interest in the client's world of feelings and meanings, conveying appreciation and understanding of whatever the client wishes to share with the therapist.

(f) Self-concept, locus-of-evaluation, and experiencing are basic constructs which emerge from the client's own interaction with the world.

(i) The self-concept is made up of the person's perceptions and feelings about self. Self-regard or self-esteem is a major component of the self-concept.

(ii) Locus-of-evaluation refers to whether the person's values and standards depend on the judgments and expectations of others, or rely upon his or her own experience.

(iii) Experiencing has to do with whether the person, in interacting with the world, is open and flexible or rigid and guarded.

(g) The Internal Frame of Reference (IFR) is the perceptual field of the individual, the way the world appears, and the meanings attached to experience and feeling. It is the belief of person-centered therapists that the IFR provides the fullest understanding of why people behave as they do, superior to external judgments of behavior, attitudes, and personality.

3. Theory of Psychotherapy

The basic theory of person-centered therapy is that if therapists offer, and clients experience, a particular kind of relationship characterized by genuineness, unconditional positive regard, and empathy, they will respond with greater self-direction and self-expression, an increased openness to inner and outer experiencing, more mature behavior and ability to deal with stress, and a concept of self that is more positive and more realistic.

4. Evolution of Theory and Practice

After Rogers assumed a professorship at Ohio State University at the beginning of 1940, he received an invitation to address Psi Chi, the psychological honor society, at the University of Minnesota, on December 11, 1940, the date often cited as the time when client-centered therapy was born. Rogers described a newer therapy which had the aim of helping individuals not only to solve their present problems but to grow in the capacity to solve future problems as well in a more integrated way, that took advantage of a general drive toward health, growth, and adjustment, that stressed emotional elements more than intellectual aspects, that emphasized the immediate situation rather than the past, and that viewed the therapeutic relationship itself as a growth experience.

The talk generated an intense reaction, both favorable and unfavorable. Rogers expanded his thinking into the book, *Counseling and Psychotherapy* (Rogers 1942), almost two-fifths of which was made up of 'The Case of Herbert Bryan,' consisting of the typescripts of eight phonographically recorded verbatim interviews. This kind of presentation was revolutionary, standing in sharp contrast to the subjective accounts of therapy being published at the time, and provided objective research data for the study of the therapeutic process.

Rogers and his students at Ohio State developed methods of classifying client statements and counselor responses, and of measuring self-regarding attitudes. The concept of self emerged as a central construct of personality organization, and great progress was made in the objective study of personality change and the behavior in therapy of therapist and client.

Research on person-centered psychotherapy advanced in a major way at the University of Chicago Counseling Center during Rogers' tenure there from 1945 to 1957. An entire issue of the *Journal of Consulting Psychology* in 1949 was devoted to a report of the 'parallel studies' project, comprising six investigations of the same group of 10 completely recorded and transcribed cases, with pre- and post-tests. The studies included measures of feelings regarding self and others, the pattern of client content (e.g., statement of problem, understanding or insight, discussion of plans), defensiveness, and maturity of behavior.

There was an evaluation of outcome using the Rorschach test, an analysis of the relationships among all these, and counselor ratings of improvement on a 1 to 9 scale. Two key findings were that (a) the measures applied to each interview provided a meaningful picture of the client's adjustment at the beginning, during, and end of therapy, and (b) there was a significant relationship between counselor estimates of success and ratings based on the interview-analysis measures. Significant relationships were not found between Rorschach results and those of the five interview measures. It was also concluded that the research methodology was applicable to therapeutic approaches generally, and that such efforts would help put psychotherapy on a scientific basis.

The 'parallel studies' project was succeeded five years later by a larger study (Rogers and Dymond 1954), which contained complete data on 29 clients seen by 16 therapists, as well as on a matched control group. It measured changes in self using the Q-technique of British psychologist William Stephenson, a sophisticated method of quantifying the way people viewed themselves at present and ideally, leading to the findings that the self-concept of clients in therapy improved significantly, and to a significantly greater degree than control group subjects, and that therapy achieved a significant increase in congruence between self and ideal. Qualitative analysis showed clients in therapy growing in their feelings of self-confidence, self-reliance, self-understanding, inner comfort, and comfortable relationships with others, with a decrease in negative feelings about themselves.

Person-centered and general psychotherapeutic theory advanced substantially with the introduction of the concept of 'necessary and sufficient conditions of therapeutic personality change' (Rogers 1957). Empathy, congruence, and unconditional positive regard were clearly defined. Capable of quantification, they stimulated hundreds of research projects. The Relationship Inventory (Barrett-Lennard 1998), an instrument measuring these conditions, has also been used in a vast number of research projects in psychotherapy and other human relations applications such as parent-child, student-teacher, and worker-employer relationships (see *Therapist-Patient Relationship*).

The most rigorous exposition of person-centered thinking, 'A theory of therapy, personality, and interpersonal relationships,' was published in Sigmund Koch's *Psychology: A Study of a Science* (Rogers 1959). A pioneering research project on therapy with schizophrenic patients and normal adults at the University of Wisconsin broke new ground in working with and doing research on this population (Rogers et al. 1967).

On Becoming a Person (Rogers 1961) included a summary of the personality and behavioral changes in therapy supported by research, an objective description of the fully-functioning person, the empirical

evidence for the conditions which facilitate psychological growth, and a description of the author's struggle to reconcile the role of scientific investigator with that of therapist operating at the height of personal subjectivity. A unique, decades-long, research effort in person-centered psychotherapy which supports Rogers' description of the fully-functioning person focuses on the understanding of personality integration, which involves physiological, perceptual, cognitive, and interpersonal subsystems (Seeman 1983). Seeman has gone outside of the usual person-centered sources, drawing on the work of analysts Erik Erikson and Heinz Hartmann, and ego development specialist Jane Loevinger, among others. His conclusions are similar to Rogers, that high-functioning persons are healthier, more efficient in their perception of reality, have superior environmental contact, high self-esteem, confidence and trust in themselves, and possess a sense of autonomy that facilitates the development of caring and generative relationships.

5. Evaluation

Orlinsky and Howard (1978) concluded that the results of relevant studies were too variable to support the Rogerian hypothesis. But they were impressed by the evidence of 13 outcome studies of patients' perceptions of therapist attributes such as nonpossessive warmth, positive regard, and acceptance; all 13 investigations yielded a significant positive correlation between such perceptions and good therapeutic outcome.

Additionally, in 1978, Orlinsky and Howard reviewed 15 studies of the relationship between outcome and patients' perceptions of their therapists as empathically understanding, and found such an association preponderantly positive, with only two or three presenting evidence to the contrary. Fourteen of 20 investigations yielded a significant positive association between therapist self-congruence and outcome, with six showing null and marginally mixed results. Nine of 10 studies focusing on the 'process' or 'experiencing' levels conceptualized by Rogers in 1957 found significant positive correlations between experiencing and good therapeutic outcome.

Orlinsky and Howard (1986) came to these conclusions about the relation of outcome in psychotherapy to aspects of therapeutic process which bear upon the conditions offered by person-centered therapists. (a) Role-investment, empathic resonance, mutual affirmation, and the overall quality of the relationship were consistently related to patient outcome in 50-80 percent of the large number of findings surveyed in this area. (b) Therapist genuineness, particularly as perceived by patients, was often but not consistently associated with better outcomes. (c) Patients' perceptions of therapist empathy were very consistently related to good outcome. (d) Therapists' warmth or acceptance toward their patients, especially

but not only as observed by patients, was quite consistently related to good outcome in therapy.

Lambert et al. (1986), analyzing scores of studies on therapy outcome, concluded that therapist personal factors such as trust, warmth, acceptance, and wisdom were crucial ingredients, even in the more technical therapies. Similar conclusions were reached by Patterson (1984) and more recently in an examination of psychotherapy outcome research studies by Bozarth (1998) with these conclusions: successful psychotherapy depends primarily on the therapist–client relationship and the client’s internal and external resources; the type of therapy is largely unrelated to outcome; the training and experience of therapists are irrelevant to successful therapy; clients who receive therapy improve more than those who do not; the evidence is weak that there are specific treatments for particular disabilities; empathy, genuineness, and unconditional positive regard are the relationship variables that correlate most consistently with effective therapy.

Watson (1984), following a careful review of the relevant research, concludes that because of methodological inadequacies, there is insufficient evidence either to support or refute the effectiveness of the ‘necessary and sufficient conditions.’ (see *Psychological Treatment, Effectiveness of*).

6. Concluding Comments

Person-centered psychotherapy has been evaluated assiduously, internally and externally, since its formulation by Carl Rogers in 1940. Its concepts and methods continue to be controversial in a field that is dominated by orientations that advocate guidance by experts. Its uniqueness in the depth of belief in the self-directive capacity of individuals and groups assures its future as a vital alternative. It continues to thrive internationally as part of a broader person-centered approach with implications for group process, education, and conflict resolution. Contributing to the health of the movement is the diversity of interpretation and implementation of Rogerian principles; it includes ‘purists’ and those who believe that a directive dimension is sometimes required. Different organizations and conferences afford the opportunity to explore these differences.

N. J. Raskin

Person-centered Research

Person-centered research here means research that focuses on the person as a functioning totality within the domain studied. The person then becomes the main conceptual unit and also often the main analytical unit. In many methodological realizations of this approach, individual patterns of values in the

variables under study become the main analytical units and subjected to, for instance, classification analysis or other types of pattern analyses. Person-centered research can be contrasted to variable-centered research where the focus is on the variable as the main conceptual and analytical unit. Variable-centered research is far more common but is not the topic of this article.

Person-centered research does not need to be quantitative and can in certain situations be carried out by case-oriented research and by using a qualitative approach. Obviously, the study of the single individual, studied quantitatively using the p-technique, is in one way person-centered, but is not normally so according to the definition given above (since the focus is usually then on relationships between variables within the individual). P-technique and time-series analysis is also discussed elsewhere in the encyclopedia. The perspective given in this article is of carrying out quantitative person-centered research on a sample of persons aiming at explaining and understanding inter-individual and/or intra-individual differences.

A very short historical overview is given of the emergence of person-centered research, followed by a presentation of the theoretical foundation of the modern person-approach. Finally an overview of common methods for carrying out person-centered research is presented.

1. The Emergence of Person-centered Research

A major type of person-centered research is the typological approach by which individuals are categorized into different types. It has ancient roots and is already reflected in the classical categorization of individuals into four basic temperaments: sanguine, phlegmatic, melancholic, and choleric. The typological view can be regarded as a reflection of a view that people are functioning wholes and that there are only a limited number of typical ways in which a functioning system can be organized. From this perspective, finding and understanding these types are important scientific goals. Creating typologies is also a reflection of a basic tendency in man of categorizing encountered phenomena.

The typological approach has been, and is still, stronger in the life sciences (especially taxonomy in biology and diagnosis in medicine) than it is in the social and behavioral sciences (for an historical overview, see Misiak and Sexton 1966). Gangestad and Snyder (1985) discussed the importance of a categorical approach in personality research and pointed to the emergence of types, each sharing a common influence (like an infectious disease caused by a specific germ). The typologies presented by Jung, Kretschmer, Sheldon, and others are still of interest today and psychiatric diagnoses in the Kraepelin tradition are

influential in clinical practice. There is also a concern with typological research in sociology, including, for instance, the search for 'ideal types' (Bailey 1994).

The word 'typology' has many meanings—see Cattell 1957 for an overview of 45 different meanings of the word. It has led to much confusion and even to resentment. This resentment was often directed against the connotation of 'innate' implied in many earlier typologies and against their subjectivity. Waller and Meehl (1998) make a number of thoughtful distinctions with regard to type and typology, preferring the use of the terms taxon for, roughly speaking, a meaningful type, and taxometrics as a generic name for (their) procedures for finding taxa. It should be pointed out that neither of these limitations apply to modern typological research within the person-approach described.

One of the first proponents of a comparatively modern person-centered research strategy was William Stern who already in the beginning of the twentieth century discussed an approach in which individual patterns in many traits were the units of analysis. Other early proponents of the importance of considering persons as functioning wholes were Kurt Lewin and Gordon Allport. A systematic approach to the person-centered study of personality development was undertaken by Jack Block based on longitudinal data. He presented an empirically based typology of longitudinal personality types and was, as far as we know, the first one to use the term 'person-approach' (Block 1971). Examples of research looking for basic categories are given by the work of Lars Bergman and David Magnusson studying stability and change in patterns of extrinsic adjustment problems, by Sigrid Gustafson studying a psychopathy-linked pattern called aberrant self-promotion, by Lea Pulkkinen, studying personality styles in a developmental perspective, by Richard Robins, Oliver Johan and Avshalom Caspi, searching for personality types, and by Ed Seidman relating typical experiential neighborhood profiles to antisocial behavior.

Perhaps the most forceful modern development of person-centered research has taken place within the new developmental science (Cairns et al. 1996). There, a holistic-interactionistic paradigm has grown strong and a new type of person-centered research has emerged (Magnusson 1999). It is focused on the study of individual development and has been called 'person-approach' (for an overview, see Magnusson 1998). Its theoretical and research strategic fundaments are described in Sect. 3.

2. Theoretical and Research Strategic Fundaments of the Person-approach

The person-approach refers to a holistic view on individual functioning and development. Magnusson and Allen (1983) summarized the essence of a person-

approach in the following way: 'The person oriented approach to research (in contrast to the variable centered approach) takes a holistic and dynamic view; the person is conceptualized as an integrated totality rather than as a summation of variables' (p. 372). A basic proposition of a holistic perspective, with consequences for the application of a person-approach, is that individual functioning and development can be described in terms of dynamic, complex, and adaptive processes in which mental, biological, and behavioral factors in the individual, and social, cultural, and physical factors in the environment are involved.

The person-approach is equally applicable to research on the current functioning of individuals and to research on individual development. Thus, it has implications for research in any field of psychological inquiry. Hitherto it has mainly been used in developmental and personality research.

For a long time the holistic view was considered to be too vague and lacking of specific content to serve as the basis for strong theories for understanding and explaining individual functioning and development. However, since 1970 the holistic model has been filled with content to the extent that it now forms a scientific basis for planning, implementation, and interpretation of empirical studies on specific aspects of individual functioning and development.

Substantively, contributions come from psychological research on mental factors and behavior and from biological and medical research on the functioning of the brain and the role of physiological factors in the total functioning and development of individuals. New findings in these areas have helped to enrich the 'black box' in S-R models with substantive contents and have helped in closing the gap between different explanations of behavior in terms of mental, biological, and environmental factors.

Contributions to the effectiveness of a holistic model as a theoretical framework for empirical research on specific phenomena, also derive from the presentation of modern models for dynamic, complex processes, particularly the general systems theory. Three aspects of these models are important for the discussion here of a person-approach.

(a) From a holistic perspective, mental, behavioral and biological aspects of individual functioning, and social, cultural, and physical factors of the environment are incorporated into one integrated theoretical framework. Thus, the role of a single variable cannot be finally investigated and understood in isolation from its context.

(b) A central principle in dynamic, complex processes is the principle of dynamic interaction (continuously ongoing reciprocal influences) as contrasted to statistical interactions in data. The new models for dynamic, complex processes provide a theoretical framework for investigating and understanding the dynamic processes of interaction of operating factors within the individual, and the continuous reciprocal

interaction between the individual and the environment in the person-environment system.

(c) For the relations among operating factors at the level of the individual, mutual dependencies characterized by dynamic interactions and non-linearities can be a characteristic feature. The same holds true for the interaction of a single individual with his/her environment. For instance, individuals' psychological and physiological stress reactions to increasing stimulation from the environment are often nonlinear. In fact, most common variable-oriented research methods are not suited for handling nonlinear relations and dynamic interactions. This is exemplified by the fact that many such methods use the correlation matrix as the data to be analyzed, a matrix which mainly reflects linear relations, not nonlinear relations and interactions.

The process of organization of current and developmental processes which takes its start at conception is guided by the principle of self-organization. Self-organizing ability is a characteristic of open systems and refers to a process by which structures emerge without 'prescriptions from the outside.' Within subsystems, the operating components organize themselves to maximize the functioning of that subsystem with respect to its purpose in the total system. At a higher level subsystems organize themselves in order to fulfill their role in the functioning of the totality. Within a specific system, say the cardiovascular system, each of the operating factors (e.g., systolic blood pressure, diastolic blood pressure, and heart rate) do not function and develop independently of the others. The specific role of each operating factor is determined by the role it plays in the system. The operating factors are organized and function in terms of functional configurations, in what will be referred to in the following text as patterns. From this perspective, the important individual differences are not to be found in differences in any single variable taken out of its context of other, simultaneously operating variables. Instead, they are to be found in differences in the patterning of operating variables in the system under investigation. This applies to all levels of organization.

For the discussion of the implications of the person-approach for an effective measurement model and methodological approach, two aspects of the organization of mental, biological, and behavioral structures and processes are fundamental:

(a) Within subsystems individuals differ to some extent in the way in which operational factors are organized and function.

(b) Only a limited number of states are functional for each subsystem and for the totality.

The number of ways is restricted in which operating factors in a certain subsystem can be organized in patterns, in order to allow the subsystem to play its functional role in the totality, and the number of ways is also restricted in which subsystems can be organized

to form the total pattern for the total organism (cf. Bergman and Magnusson 1997). This view implies, among other things, that the studied complex systems have inherent restrictions which lead to (a) certain states being frequent or typical and (b) other states not occurring. The first aspect has been much studied and provides a motivation for the search for types. The second aspect has been much less studied but can also be of importance: What does not occur but, in principle, could occur contains information about how the system under study functions (cf. the concept of 'white spots' as discussed by Bergman and Magnusson 1997).

As emphasized above, the person-approach is a theoretical perspective. As such it forms the theoretical framework for the planning, implementation, and interpretation of specific substantive issues. This implies, among other things, that it has to be distinguished from the methods applied for treatment of data within the perspective of a person-approach. However, in most cases, pattern-based methods emerge as the most natural method choices. A brief overview of a selection of such methods is given in Sect. 4.

3. A Selection of Methods for Carrying out Person-centered Research

3.1 Classification and Cluster Analysis

It was mentioned in the introductory section that classification is a basic approach for carrying out person-centered research. Before discussing different types of classification analysis a few basic properties of such an analysis should be mentioned. In most forms of classification analysis the basic data are contained in the similarity or dissimilarity matrix between all pairs of subjects. Similar subjects are then grouped together in the classification analysis. The (dis)similarity between each pair of subjects could be a subjective rating but is most commonly calculated according to a formula that takes into account the (dis)similarity of the profiles of values in the variables for the two subjects. One common formula that takes into account differences in both level and form of the value profiles is the averaged squared Euclidean distance. It should be pointed out that the choice of (dis)similarity coefficient usually has important consequences for the results obtained in the classification analysis and that this choice should always be made on the basis of considerations in the specific case. The measurement characteristics of the different variables must be considered since the results of many methods are not invariant under linear transformations of the involved variables.

A classification can be achieved in different ways:

(a) It can be strictly theoretically derived as in the construction of ideal types.

(b) It can be totally empirically driven as in cluster analysis where subjects are classified together in clusters on the basis of their profile similarity. This type of classification approach is the most common one and is described.

(c) Some kind of model-based quantitative approach can also be used.

Examples of (c) are latent structure analysis and latent class analysis, originally proposed by Paul Lazarsfeld, where a number of latent classes is assumed and then the fit to the empirical data is tested and parameters are estimated (Goodman 1974). If the model holds, all relationships between variables within a latent class should disappear (the assumption of local independence).

3.1.1 Cluster analysis. In cluster analysis, a large number of methods are available for classifying objects on the basis of their (dis)similarities. Major types of cluster analysis are hierarchical methods (agglomerative or divisive), partitioning methods, and methods that allow overlapping clusters. Within each type of methods a variety of specific methods and algorithms exist. Perhaps the most common form of analysis is the agglomerative hierarchical cluster analysis. This group of methods starts with each of the n subjects being its own cluster. In Step 1 the two most similar subjects are joined to form one cluster giving in all $n-1$ clusters. In Step 2 the two most similar clusters are joined to form one cluster, giving in all $n-2$ clusters. The process is repeated until every subject is in one and the same cluster that occurs at Step $n-1$. The result is a hierarchical classification tree. Often the researcher concentrates on one cluster solution with a fairly small number of clusters and each cluster is described by its profile of means in the variables studied (called the cluster centroid). All members in that cluster should have profiles similar to the centroid. Different specific methods of hierarchical agglomerative cluster analysis have different rules for how to decide which two clusters are most similar. For instance, in the single linkage (= nearest neighbor) method the similarity between two clusters is given by the (dis)similarity of the two subjects, one from each of the two clusters, that are most similar. What method of cluster analysis is most appropriate of course, depends on the specific situation. Evaluations of the sensitivity of different clustering algorithms to the effects of errors of measurement and of the ability to recover a known cluster structure indicate that, as expected, no method appears to be generally superior to the others. Methods that often see to perform well include Ward's minimum variance method and average linkage cluster analysis (two hierarchical methods), and k-means relocation analysis based on a reasonable start classification (Morey et al. 1983). More recently, methods based on so called Beta-

flexible clustering have been suggested. For an overview of methods for cluster analysis see Gordon 1981.

3.1.2 Should all subjects be classified? It has long been recognized that multivariate outliers may disturb the results of cluster analysis and it has been suggested that in some situations the coverage must be less than 100%, i.e., not everybody can be classified. Bergman (1988) drew attention to the fact that there often exist a small number of 'unique' individuals, not similar to any other subjects that should not be forced into a cluster. He presented a procedure, RESIDAN, for *a priori* identifying and analyzing separately what he calls a residue of unclassified subjects. In a subsequent residue analysis, rare or non-existent patterns are studied which may be of theoretical significance (cf. the discussion about 'white spots' in Sect. 3).

3.1.3 Classification in the study of individual development. Important and intriguing methodological problems for person-centered research occur when studying individual development. A variety of approaches are available.

(a) Directly analyzing longitudinal patterns of values in variable profiles have often proved disappointing. If only profile form is studied, a direct longitudinal classification might work better than otherwise, since the amount of information that has to be summarized by the cluster membership variable is drastically reduced. An example of the usefulness of a longitudinal classification strategy in this situation is given in Block's (1971) study of longitudinal personality types.

(b) The analysis of cross-sectional patterns followed by linking over time is simpler and also often more robust than most other methods. One standard method of this type is called Linking of Clusters after Removal of a Residue (LICUR, Bergman 1998). LICUR is suitable in situations where both form and level of the profile is considered to be of importance. It includes procedures for removing a residue before the cluster analyses that are performed at each age separately and procedures for deciding the number of clusters. The results of the cluster analyses are linked between adjoining ages by cross-tabulating the classifications obtained at the two ages and it is tested for over frequented and under frequented cells (i.e., cluster membership combinations occurring more or less frequently than expected by chance). LICUR is applicable in a large number of settings, for instance when different variables are measured at the different measurement occasions and during periods of dramatic developmental shifts. Model-based alternatives to LICUR are provided by longitudinal extensions of latent class analysis, for instance latent transition analysis developed by Collins and Wugalter (1992).

3.2 Some other Approaches for Person-centered Analyses

3.2.1 Identifying a set of typical classes. Sometimes the interest is not in a complete classification but rather in identifying homogenous subgroups of subjects ('dense points' in a multivariate space) believed to indicate system states that are in some way 'important.' It is then believed that many subjects have entered a stable 'functioning' system state with a characteristic value pattern and that there are only a limited number of such states. Frequent typical patterns are regarded as indicators of such optimal states. One may also be interested in recognizing patterns that *a priori* are considered as 'important.' For overviews of various techniques relating to these issues see Young and Fu (1986).

3.2.2 Studying all possible patterns using configural frequency analysis. Configural Frequency Analysis (CFA) is a set of methods for studying all possible value patterns for a set of studied variables. The involved variables have to be discrete and are often dichotomized to make the number of value patterns to be examined manageable. CFA was originally suggested by Gustav Lienert. Lienert and his co-workers have developed CFA in a number of ways and in Germany it has become a research tradition. For a basic introduction see Krauth and Lienert (1982). A more recent overview is given by von Eye (1990) who also has contributed to various newer developments of CFA. The idea of types in a psychiatric setting was elaborated by Joachim Krauth who pointed to the importance of identifying combinations of variable values that emerge above chance level. His line of reasoning relates to the discussion about optimal systems states and designs as being more frequent than other states and designs. For further information on CFA, see von Eye (1990).

3.2.3 Analyzing specific properties of patterns. Instead of considering the complete value patterns in a pattern analysis, specific aspects of the patterns can be highlighted. Two such analyses are the following:

(a) In some cases the maximum and minimum scores of the subject's profile of scores are at focus. The variable taking the maximum value and the variable taking the minimum value may be seen as the essential features of the profile with the other scores providing the background. Of course, this implies that the different variables are scaled in a way that allows for comparisons between variables.

(b) The degree to which a subject's profile is even or uneven can be studied in different ways and an obvious measure of profile scatter is its variance around the mean of the scores in all variables constituting the profile.

3.2.4 Abstracting group memberships from qualitative information. A good example of this approach is the work done by Singer et al. in linking life histories to mental health outcomes. Richly detailed descriptions of individual lives form the input data for a procedure for discerning generalizable features of aggregates of multiple lives.

4. Some Final Comments

We believe that the theoretical perspective included in the person-approach presented above provides person-centered research with a useful meta-theoretical framework. But to reiterate: a person-approach should not be confused with a methodological approach using pattern analysis although such methods often are natural within a holistic orientation.

Sometimes reality may not be continuous but may rather operate to produce more or less discrete types. Or put differently: only certain configurations of system states are in some way optimal and become stable and often observed. A discussion of this issue was given in Sect. 3. It can then be argued that in person-centered research, methods for pattern-based analysis are often more useful than standard variable-based methods. Many common variable-based methods do not handle interactions well and in many situations pattern-based methods are more naturally used for this purpose. In fact, taking interactions seriously, such an approach, focusing on variables, tends to become very complicated. Lee Cronbach even made the metaphor of entering a hall of mirrors when one pursues such a goal.

It has sometimes been claimed that results from many methods used in person-centered research, for instance cluster analysis, are untrustworthy. In order to evaluate the validity of results from such studies two aspects should be discussed separately: (a) the technical aspects of the methods applied and (b) the appropriateness of the application of these methods in different settings. There is nothing wrong technically with any of the major methods used to carry out person-centered analysis. The problem arises when a method is inappropriately applied. Inconsistent results are often caused by the use of a clustering procedure that does not match the combined requirements of the problem under study and the data available. Important considerations for obtaining useful results from a cluster analysis are: (a) That the variable profile under study adequately summarizes the information *Gestalt* of interest; (b) that the values in the different variables are comparable and an appropriate (dis-)similarity coefficient has been chosen; (c) that a sound clustering algorithm has been chosen; (d) that only variables are included in the value profile which have a reasonably high reliability and, if finding hom-

ogenous clusters is the focus of interest, the profile is constituted by only a limited number of variables; and (e) that in many cases not all subjects should be classified. A number of validation procedures are available for studying the results of a classification analysis.

Two issues that are sometimes confused in person-centered research are the question about identifying generic classes ('natural clusters') and the question about ascribing the subjects in the sample to the appropriate class. It is a general experience that the second purpose tends to be more difficult to achieve. If the purpose is to identify typical value profiles that frequently emerge in different settings, one way of validating these typical profiles is to compare centroids between different samples/split-halves. Those that replicate might be regarded as types. These typical profiles need not, of course, together comprise a total classificatory system that encompasses everybody in a specific sample. On the contrary, the usefulness of a partial typology should be stressed since it can often be a more realistic goal. For instance, methods for determining how well the (dis)similarity matrix is represented by the classification solution are sometimes erroneously used for evaluating to what extent the first purpose has been achieved. Such methods are mainly relevant when the study of individual class membership is at focus.

Applying variable-oriented methods it is often assumed that (the same) linear relations approximately hold over individuals and that the essential features of a multivariate data set are captured by, for instance, the correlation matrix. This enables the researcher to use modern powerful statistical methods to construct models of data that are testable within the confinements of these basic assumptions. However, as was pointed out in Sect. 3, in settings when these assumptions cannot be assumed to hold a person-centered approach emerges as an alternative. It is natural that the recognition of multivariate complexity and higher-order interactions that follows with this perspective also makes it extremely difficult to formulate a coherent testable model of the data. Of course, this does not mean that person-centered research needs to be explorative in its methods. Theoretical considerations will lead to expectations about, for instance, types and antitypes and about typical developmental streams which are testable using various methods.

Finally, during the last decade person-centered research has received increased attention. For this we believe there are sound motives, as explicated in the section about the person-approach. In some situations one can trace a disappointment in the meager outcome in the understanding of a studied process given by even sophisticated variable-oriented methods. Applied with good judgment, person-centered research may then offer a deeper insight in how a system works. This applies to systems at the level of the individual as well as at other levels.

L. R. Bergman and D. Magnusson

Personhood, Anthropology of

'The Anthropology of Personhood' compasses the definition and study of three conceptual terms: 'person,' 'self,' and 'individual.' It is the exploration of the nature of the identity of the individual actor and the relationship between that identity and the symbolic forms and material practices of different sociocultural milieux.

On neither the meaning nor the implication of the above conceptual terms, however, can significant disciplinary consensus be found; a number of writers have addressed definitional issues directly (Harris 1989), but large disagreements remain. The dissension is perhaps understandable when one considers that what is fundamentally at issue is the nature of individual consciousness, and its manifestation—emergence, development, and construal—in different times and places. What is the relationship between 'nature' and 'nurture' in this context: between consciousness as a biological given and as sociocultural construct; between consciousness as privately experienced and as publicly validated; between consciousness as uniquely embodied and as collectively elicited and shared?

The position taken in this article is that an anthropological study of personhood must be careful to distinguish between what may be termed 'individualism' and 'individuality': roughly, between the conventional conceptualization of individual actors in particular settings on the one hand and their personal experience on the other. Much of the conceptual difficulty which the discipline has experienced arises from a conflating of these two, a confusion which goes back to Durkheim.

1. Social Structure and System

1.1 The Durkheimian Individual

Durkheim conceived of human beings as *homo duplex*; on one side there was the biological and personal (comprising the individual body with its material senses and appetites) and on the other the social and moral (the conceptual and conscientious). The individual thus led a double existence: one rooted in the physical organism and one (morally, intellectually, spiritually superior) in a social organism of collectively and uniformly held ideas and practices. Between the two there was ongoing antagonism and tension, but through inculcation into a public language and culture, humankind was capable of rising above mean (animal) 'individuality' and becoming part of a collective conscience in which the (sacred) traditions of a society were enshrined. If individuals were indeed conscious of themselves as individuals, then this was

equally a product of their socialization in a collective conscience; 'individualism' was a social product like all moralities and all religions.

From Durkheim's (structuralist) descendants a collectivist narrative was elaborated which conceptually subsumed the individual actor within sociocultural contexts. Mauss (1985) took it upon himself to detail how experience was constituted by cultural categories, and thus how society exerted its force on the physiological individual. He outlined a purported evolution in individual consciousness which could be tied to the particular forms of social structuration. First, comes the tribal stage of *personnage*, where individuals are conceived of as ephemeral bearers of a fixed stock of names, roles, and souls in clan possession; having no existence independently of the clan, individuals possess no inner conscience. Next comes the Classical stage of *persona* where individuals are conceived of as independent and autonomous citizens of a state; they are responsible, legal persons but still they possess no inner life or identity beyond the civic. With the rise of Christianity comes the stage of *personne*; conceived of as indivisible and rational, possessing a conscience, indeed, a unique sacred soul, the individual now serves as the foundation of all political, economic, and legal institutions. Finally comes the peculiar Western stage of *moi*: the individual as a 'self,' with self-interestedness and self-knowledge, as validated by modern institutions of psychological science.

Beginning with the assumption that sociocultural holism represents the paradigmatic form of human consciousness and experience, Dumont (1986) set out to plot more precisely the origination and progression of the singular Western idea of the autonomous individual as bearer of supreme moral value by comparing it with the Oriental 'archetype.' The Christian *personne*, he suggests, is reminiscent of the Hindu figure of the 'world-renouncer,' someone who seeks ultimate truth by forgoing the world in favour of his own individual spiritual progress. In the world-renouncer one finds a Western-like individualist for whom society has lost its absolute reality, and who, despite the constraining interdependence Indian society ubiquitously imposes on its members, has become self-conscious and self-sufficient. The evolution of the Western individual and the 'substitution' of self for society as absolute value marks the triumph of a (Christian) religious ideology in which worldly renunciation becomes the collective norm. Christ's teaching that man possesses a soul which absolutely transcends the world of social institutions and powers (which is absolutely individual in relation to God and meets others' only in God) engenders a community of 'outworldly' individuals who meet on earth but have their hearts in heaven. Nonetheless, Dumont concludes, the evolution need not end there; in the wake of such movements as multiculturalism, nationalism, fascism, and Islamic fundamentalism, the cultural

future of individualism is, to say the least, unpredictable.

Characterizing the above, 'Durkheimian,' line of thought, in short, is the idea that the individual actor of Western society is the result of a recent and exceptional historico-cultural development. The concept of the 'individual' and its moral and social significance is absent elsewhere, with no *a priori* differentiation being made between individual and role, between self and society. Learned in this paradigm, moreover, it is not surprising that in much anthropological reportage on the person one finds a denial of individualism and little discussion of individuality. Inasmuch as 'the individual' exists, it is as a particular manifestation of 'the person'; it is not individuals who are seen to be diverse so much as the working parts of the complex social systems of which they are components and conduits. Individuals, in short, become collective constructs within the contexts of specific cultural ideologies and social practices, their psyches emanations of certain pre-given and prestructured life-worlds of socialization.

For instance, Strathern (1988) describes Melanesian personhood not in terms of individuals—distinct actors with discrete emotions, awareness and agency—but 'dividuals': beings constituted by properties, goods, and substances as these are ongoingly exchanged with others. The Gahuku-Gama, Read (1955) elaborates, are conscious of themselves only as members of common categories of relations; rather than, say, 'friendships' between unique individuals there are only relationships between socially defined positions. Similarly, Myers (1986) records Australian Aboriginal 'emotions' not as pertaining to deep-psychological experiences of the individual but as cultural evaluations of people and circumstance which persons must make in order to live in fluxional social settings. Geertz (1973, pp. 360), finally, relativizes Western conceptions of the autonomous individual by emphasizing the collective role-playing fundamental to the Balinese *habitus* of the person. Culture, Geertz suggests, translates into symbolic 'control mechanisms' by which the breadth and indeterminateness of actors' potential social lives are programmatically reduced to the specificity and narrowness of their actual ones.

In sum, a Durkheim-inspired anthropology of personhood has eventuated in comparative enquiries into the diversity of sociocultural conceptions of the human individual, how these conceptions connect with other sociocultural 'institutions' (family, law, exchange), and how these different ways of conceptualizing determine differences in experience. 'Personhood,' on this view, amounts to 'those culturally constituted and socially conferred attributes, capacities and signs that mark a moral career and its jural entitlements in a particular society' (Poole 1998, p. 842). 'Selfhood' refers to a human being as a locus of experience, as this experience is culturally allocated

and defined—usually as relational, socially embedded, and sociocentric. ‘Individual’ compasses an actor’s uniqueness to the extent that this latter is realized in certain collectively structured life-worlds.

1.2 The Non-Durkheimian Individual

There have been exceptions to the Durkheimian line, nevertheless: ethnographies and analyses which deny the priority (ontological, developmental, historical) of the societal in its causing and conditioning of individual experience. Tracing the ‘origins of English individualism,’ Macfarlane (1978) sets out specifically to refute those theorists who would see individualism as a recent socio-cultural development—whether epiphenomenal upon religious or Renaissance or Enlightenment or capitalistic or industrialistic thinking. For:

the majority of ordinary people in England from at least the thirteenth century were rampant individualists, highly mobile both geographically and socially, economically ‘rational,’ market-oriented and acquisitive, ego-centred in kinship and social life (1978, p. 163).

In New Guinea, meanwhile, Burridge (1979) describes how most people are ‘individuals’ and ‘persons’ in different respects and at different times, where ‘persons’ may be understood as those who realise given sociocultural categories, prescribed by traditional morality and the social order, while ‘individuals’ are those who use their perception and intuition to create anew. If persons are products of current sociocultural conditions, then individuals exist in spite of them. Each ‘spatially bounded organism’ is able to switch between these two modalities, Burridge concludes, such individuality representing an existential imperative which pre-exists culture. This also accords with Wikan’s (1990) reappraisal of the Balinese, where the institution of cultural norms of personal composure, grace and placidity do not obviate the individual emotional effort and will be recognized as necessary to effect and sustain their appearance.

An emphasis on individual actors, their personal experience and agency, similarly found expression in early anthropological theorists of consciousness (such as Gregory Bateson and Anthony Wallace), in the transactionalism with which Fredrik Barth (and also F. G. Bailey and Robert Paine) developed Leachian insights into instinctually ‘interested’ individuals, in the work of network analysts (such as John Barnes and Ulf Hannerz), and in the burgeoning of studies within interpretive anthropology more generally which focus on the constructions of experience made by particular individuals in interaction. These accord more with Weberian sentiments that collectivities must be approached solely as the resultants and modes of organization of the particular acts of individual persons, since it is they who remain the upper limit and the sole carrier of meaningful conduct.

Notwithstanding, structuralist and poststructuralist discourses still denigrate an anthropological sensitivity of this kind as ‘methodological individualism’: as an erroneous couching of explanation in terms of individuals’ characteristics, their behaviors, and interests, such that the ‘foundational’ conditions of sociocultural reality are obscured. The center ground of anthropology, it may be true to say, remains the preserve of ‘methodological collectivism,’ positing social phenomena as determined by factors which bypass individual rationality, and hence envisaging cultural development quite independently of individual consciousness. There is a continuing insistence, in other words, that the distinction between the individual and the societal is specific to the West and must be collapsed in favor of the latter—or at least of ‘social relations’—for anthropology persuasively to encounter cultural others.

On the other hand, there is a growing insistence that it is a peculiar ethnocentrism for anthropologists to fail to allow in the ‘others’ we study the personal complexity which we recognize in ourselves: as both individuals and persons, role-players and rebels, conventional and creative. The anthropology which has sought most deliberately to keep this truth in view may be termed ‘existential’ or ‘phenomenological,’ after the philosophical traditions associated with such writers as Kierkegaard, Nietzsche, Husserl, and Sartre (Rapport 1997). It sets out with very different tenets and intentions from the ‘sociological’ orientation towards social structures and systems predominant above, privileging instead individual existence and experience.

2. Existence and Experience

To become human is to become individual, Geertz (1973, p. 52) has admitted, adding that we become individual in an environment of sociocultural forms and patterns in whose terms we give form, order, direction, and point to our lives. The important question which this raises is the precise relationship between sociocultural forms and the individual lives lived by them. Becoming human and individual in an environment of common sociocultural forms need not eventuate in becoming ‘the same’ as others, or even necessarily comparable, nor becoming after a deterministic or directly influenced fashion. For in this becoming, energy, agency, intention, and interpretation can be seen to remain properties of self-conscious subjects; indeed, it is individual agents who are responsible for the creation, animation, deployment, and development of systems of forms in their usage of them.

An intrinsic dichotomy between individual and world is often eschewed as a peculiarity of ‘Western’ sociocultural milieux, as we have heard, and hence as methodologically and analytically inapplicable. This is hardly defensible. Human beings may be

socioculturally situated, but they are also, always, interpretively autonomous—responsible for a ‘personalization’ of the world—and inexorably and inevitably (by) themselves. It is not good enough simply to say that only Western culture valorizes the concept of the individual—as ‘individualism’—and therefore only in Western society do individuals act distinctively—with ‘individuality.’ For, while the former might be said to describe a particular socio-cultural form of behavior (the pursuit of self-distinguishment), the latter concerns a condition which is a human universal: by virtue of a unique consciousness, each of us perforce engages with the world as other and is possessed of distinct perspectives upon it.

Individualism, more precisely, pertains to a specific historico-cultural conceptualization of the person which includes such notions as: the ultimate value and dignity of human individuals, their moral and intellectual autonomy, their rationality and self-knowledge, spirituality, right to privacy, self-sovereignty, and self-development, and their voluntary contracting into a society, market, and polity. Individuality, by contrast, refers to that unique awareness, and awareness of awareness, which is the mark of human embodiment. It is the universal nature of existence that human beings engage with others by virtue of discrete sense-making apparatuses (nervous systems and brains); they possess discrete centers of perceptual activity in discrete bodies. Furthermore, the human body (and in particular the brain) gives rise to knowledge of the world, to a perspective upon the world, which is inherently individual: human beings come to know themselves within the world by way of cognitions and perceptions, thoughts, feelings, and imaginings, which are unique to them (Edelman 1992).

Not only is there an individuality intrinsic to human consciousness but also to human agency. For, it is in terms of his perceptions that an individual comes to act, each individual becoming a discrete centre of motivation and intention. Not only is the individual’s being-in-the-world universally mediated by very particular interpretative prisms which distance him from it, then, but while intrinsically ‘of the world,’ the individual inexorably comes to know the world, and act towards it, as ‘other.’ Individuals experience and interpret (and experience themselves interpreting) and therefore they are.

An individuality of consciousness and agency is current whatever the provenance of individualism as a cultural norm. Individuality is the human *a priori*, the physical-psychical basis on which all human knowledge of the world, all creativity within it and all activity upon it, rests (including the creation and representation of sociocultural milieux). Individuality remains consequential, that is, whether or not individual consciousness is an item of collective discourse, whether or not individual reflection is publicly eschewed, and whether or not individual distinctive-

ness is disparaged through the institutionalization of a fund of common behaviours (concerning, for instance, notions of the person). The experience of self is essentially distinct from sociocultural representations of self (cf. Spiro 1993).

Finally, an existential anthropology of personhood can hope to ‘decolonize’ (Cohen 1994) the individual human subject both from overdetermining cultural conditions and overweening social institutions (discourse, language-game, collective representation, social relationship, *habitus*, praxis), and from their holistic and hegemonically minded social-scientific commentators. It can take into account both the individual agency which brings sociocultural milieux to life and also the common sociocultural forms and practices by which individuals coordinate their activities and world-views within these milieux. Retaining respect for individual cognitive processes it apprehends the ambiguous interface between convention and individuality, and portrays sociocultural milieux as comprising, constituted by, individual difference: human individuals making a diversity of meaningful worlds by way of a commonality of cultural forms. In this way, an existential appreciation is promised of the ‘individuals’ behind the ‘persons,’ and of that consciousness of ‘self’ by which the disjunction is mediated.

Personnel Selection, Psychology of

The term personnel selection has a scientific as well as a practical meaning. Scientifically, personnel selection indicates the methodology of developing and evaluating psychological methods to assess task-related qualifications which permit predictions of occupational success, job-related classification, and application of means of personnel development, including models and tools of personnel decision making. Thus, it should be referred to as personnel selection research. In organizational practice, personnel selection means the endeavor of choosing those individuals from the group of applicants who best meet the demands of the job and the organization. Although all kinds of job-related consulting for individual occupational and organizational choice are served as well by the same psychological methods, in English terminology the term personnel selection generally is used for the whole bundle of research, development, and application for all purposes in this context. Following this, this article will discuss the most important aspects relevant to these issues.

1. Comparison of Person and Job

Occupational or job-related qualification, understood as the probability of success, basically means 'who is suitable and what for?' That is, the target groups or individuals are to be defined just as well as the target

positions. The requirements of the tasks or positions are to be established, and the necessary characteristics of the job-holders have to be derived on that basis. For very specific requirements, diagnostic methods are available or will be developed, or adapted, in order to measure and to compare job-relevant traits or abilities. Besides performance criteria, other indicators of occupational success can be formulated as objectives of the diagnosis, namely job and work satisfaction, health and well-being, or the tenure in the organization. Consequently, in addition to task analysis, the potential for satisfaction of the job in question has to be determined and compared with the interests and needs of the individuals.

Aside from determining the present requirements, an attempt can be made to estimate what kinds of changes in the requirements are to be anticipated; furthermore, an undeterminable amount of change has to be expected. The required development potential of a person should correspond to the foreseeable changes and offer the prospect to be up to future developments of an uncertain nature. Predictions are difficult in this area; however, some characteristics turned out to be relevant to success in most occupational contexts. Based on these general findings, it is necessary to compare person and job on three different levels (Fig. 1).

Different methods of task and job analysis are available for the investigation of occupational requirements. For our context, the most important kinds of requirements—not always clearly separable—are formulated as trait requirements (e.g., abilities and interests), behavioral requirements (e.g., skills and habits), qualification requirements (e.g., knowledge and skills), or as outcome requirements (e.g., problem solving and quality standards). In most cases the assessment of requirements is conducted by observation or by means of interviews or questionnaires.

2. Job-relevant Characteristics

The required characteristics of the job candidate are investigated, as far as feasible and appropriate, as they apply to the job-specific requirements. However,

Occupation/job	Individual
Requirements	Abilities, skills, and knowledge
Satisfaction potential	Interests, needs, and values
Changes	Development potential and general success-relevant characteristics

Figure 1
Comparison of person and job on three different levels

several characteristics also proved to be relevant predictors of occupational success. Preceding all is general intelligence, for which meta-analytical methods (Hunter and Schmidt 1990) provided evidence which showed that it is a valid predictor of achievement for practically all occupational fields (the effect of intelligence on work performance is mainly due to the ability to acquire job knowledge). As opposed to this, global personality traits such as extraversion and openness to experience have not shown to possess general validity. However, restricted variance in applicant samples may be responsible for this finding, adding to the problem that personality inventories usually lack job orientation. Among the global personality characteristics, the trait 'conscientiousness' seems to be of general relevance. In a meta-analysis using only European samples, Salgado (1997) found emotional stability (neuroticism) also to be a valid predictor for all jobs and criteria. While validity coefficients for these general traits turned out to be rather low, some narrower and less well-researched personality constructs showed higher validities at least for several occupational groups. Among these traits are: achievement motivation, self-confidence, and dominance. The highest predictive validity for a non-cognitive trait has been found for 'integrity' (Ones et al. 1993), while its construct validity is still a controversial issue. Approaches to determine the interaction of several characteristics—especially those belonging to different diagnostic taxonomies—are only in the beginning. The application of structural equation modeling and related statistical methods should lead to substantial progress (Schmitt and Chan 1998).

3. The Trimodal Approach to Personnel Selection

The distinction of three general methodical approaches is helpful for the classification of diagnostic instruments: the *trait approach*, the *simulation approach*, and the *biographical approach* (Schuler 2001). Each one of these approaches pursues a partially independent validation logic and corresponds to specific methods of personnel assessment. With the trait or construct approach, characteristics are measured which are assumed to be relatively stable, e.g., conscientiousness and verbal intelligence. In order to assess these traits as homogeneous constructs, psychological tests are being used as typical instruments. In this case, construct validity is at the core of successful measurement. The objective of the simulation approach is the assessment of behavior similar to that required at the workplace; the appropriate validation strategy is the one which aims at representativeness or *content validity*. A typical form of measurement is the *work sample*. The third diagnostic principle is the biographical approach, although it cannot always be

Figure 2

The trimodal approach to personnel selection

sharply distinguished from the other approaches. Typical assessment methods are biographical questions which can be presented in paper-and-pencil instruments (questionnaires), or in verbal form during an interview. Currently not in use, but a potentially fruitful method is the ideographical analysis of biographies (Fig. 2). For practical personnel selection, this means that in most cases multiple procedures are superior to cover complex requirements situations.

4. Instruments for Personnel Selection

First, the section discusses different types of single procedures, subsequently more complex procedures are presented (for a more detailed report, refer to Schmitt and Chan 1998, Schuler 2001).

4.1 Tests

Psychological tests are standardized routinely used methods for the measurement of individual behavioral characteristics, from which conclusions can be drawn pertaining to the individuals' traits or their behavior in other situations.

In scientifically controlled aptitude measurement, tests are the most commonly used instruments. They are applied to practically all occupational fields and job-relevant abilities. The most important kinds of tests used in personnel selection are:

- (a) Tests of general cognitive ability (intelligence);
- (b) Tests of specific cognitive abilities;
- (c) Tests of attention and concentration;
- (d) Tests of the sensory and motor abilities;
- (e) Other achievement tests;
- (f) General personality tests;
- (g) Specific personality tests;
- (h) Tests of attitudes, motivation, and interests.

Numerous tests have been published and are available from the test publishers. However, large organizations (such as the Federal Labor Agency, industrial companies, the military) often employ methods specifically designed for their purposes. The number of applications of these methods depend on the relevant occupational group. Figure 3 (data from 1990) shows that the extensiveness with which large companies use tests differs substantially between European countries.

4.2 Work Sample Tests

Work sample tests, being the prototype of simulation-oriented diagnostic tools, are standardized tasks which require assessees to carry out success-relevant occupational behavior. A high similarity of predictors and criteria is intended. The construction of work samples generally follows the same principles as that of psychological tests. A substantial difference is that it is largely done without 'translating' the occupational tasks into trait requirements. Rather than inferring a predisposition (trait) from a 'sign' (test behavior), conclusions are drawn from a sample of behavior for similar future behavior (Robertson and Kandola 1982). Examples are the preparation of a workpiece by a mechanic or a 'test lecture' by a teacher. A new class of work samples has been created by using video technology and virtual reality.

The use of computer-based procedures for psychological testing is rapidly growing (Booth 1998). The simulation of complex and dynamic problem solving tasks in scenarios requires the application of computers. These types of problems, originally developed in cognitive psychology, confront the applicant with a virtual environment where he/she has to control a system so that certain objectives will be reached. Hereby, the outcome variables (e.g., sales) as well as process variables (e.g., decisions), which are characteristic of a person's working behavior, can be observed.

There is also a special type of work samples that can be described as a kind of hidden intelligence tests, e.g., *job knowledge tests*. As construct validation research showed, cognitive ability is the primary determinant of knowledge acquisition. An extensive meta-analysis by Dye et al. (1993) proved job knowledge tests to be among the most powerful predictors of occupational success, especially in cases of high similarity between jobs and tests, and high job complexity.

4.3 Biographical Information

The basic principle of the biographical approach in personnel selection is the direct prediction of future behavior from past behavior. Application documents are being evaluated primarily with respect to that sort of information, although other (e.g., formal) aspects also require attention. Essential biographical elements are the curriculum vitae and references that contain

information about job experience and achievements, as well as school and university grades. Methods of analysis to gain a maximum of information out of application documents have not been developed yet.

Prototypical for the biographical approach is the biographical questionnaire. These instruments are often difficult to distinguish from personality tests. In comparison to personality items, biographical items are generally related to the past, and they typically concern behavior and verifiable events. Classical principle of questionnaire construction is the validation of each item or even of each response alternative within a multiple-choice item with respect to external criteria. This results in a task-specific and often also organization-specific item selection—and as a consequence in limited generalization. For this reason, the 'blind empirical' approach is often combined with a rational approach which is requirement- and construct-related (Stokes et al. 1994). In most cases the most straightforward sources of performance-related biographical information are the level of education, school, and college grades. While the level of education is of high predictive value, school grades provide highly valid information for later educational performance, but the validity for predicting job performance is only moderate (Roth et al. 1996). Yet, in the 1980s and 1990s, predictive validity has even decreased for High School grades (Schuler 2001).

4.4 Interviews

Typical modes of employment interviews vary from a totally free conversation over partly structured to fully structured variants using standardized procedures, questions, and response evaluation. Ensuring interview validity can best be achieved by constructing the interview tool closely adapted to job requirements, standardizing questions, providing examples of response evaluation on behaviorally anchored rating scales, and combining several types of questions. The construction of interview questions can follow the same psychometric principles as test construction. Among the more elaborated types of interviews are the *Situational Interview* (Latham et al. 1980) and the *Multimodal Interview* (Schuler and Funke 1989). By means of the latter, it could be demonstrated that both construct- and simulation-oriented principles of assessment can be realized in an interview, as well as the biographical principle. Moreover, a sequence of structured and unstructured interview components takes account of a candidate's preferences for selection instruments that allow behavioral control, i.e., situations of low structure.

4.5 Multiple Procedures

The purpose of multimodal assessment procedures is to take into account a heterogeneous requirement

Note: Germany (D), Great Britain (GB), France (F), Spain (E), and the Benelux (BEN). Contrasted are the use of personality tests (■) vs. ability and intelligence tests (□) in percent of companies.

Figure 3

Application of psychological tests in several European countries

constellation by combining different methods and diagnostic principles. Basically, all types of single procedures can be combined; however, meta-analytical calculations show that noncognitive predictors can provide substantial supplements only in a few cases, i.e., incremental validity, in addition to intelligence tests. The most important of these predictors are work samples, specific personality tests, and structured interviews. As multiple selection procedures for supervisors and trainees, *assessment centers* are often used (Thornton 1992). They usually consist of work-samples such as group discussions, organizational tasks, presentations, and dyadic role-plays. Characteristic for an assessment center is that several applicants participate at the same time, and that the evaluation is carried out by several independent assessors. As far as the procedure succeeds to grasp the entirety of a person's potential for future development, we speak of *potential analysis*. Where reliable criteria are available, single components of multimodal procedures can be weighted for the calculation of a total score (e.g., by multiple regression).

5. Evaluation of Selection Instruments and Procedures

The evaluation of personnel selection procedures has to examine test theoretical criteria, especially objectivity, reliability, and validity. In addition to these, instruments have to be assessed according to organizational efficiency or advisory efficiency, to social validity as well as to further ethical and legal aspects.

5.1 Validity

Among the criteria of psychometric quality, validity is the most important, the others are necessary, but not sufficient conditions for validity. Among the variants of validity (or strategies of validation), *predictive validity* plays a crucial role, since the objective usually is the prediction of future occupational success. The following diagnostic procedures demonstrated good

or sufficient validity (Salgado 1999, Schmidt and Hunter 1998): tests of general intelligence, work samples, job-related structured interviews, biographical questionnaires, some specific personality tests (integrity, conscientiousness, achievement motivation), and multimodal procedures (assessment center, potential analysis); tests of job knowledge and assessment of job performance are in a similar range. It must be noted that there are some moderating conditions (e.g., the validity of biographical questionnaires for young persons is low) and that validation leads to different coefficients for different measures of success—i.e., supervisory assessment, position level, income, assessment of potential. The aspect of *content validity* is important especially during the steps of instrument construction, that of *construct validity* in the examination of the psychological meaning of test scores.

5.2 Organizational Efficiency

Organizational efficiency is operationalized by aspects of practicability; these are, above all, the *expenditure* of the procedure, the required competence for its application, and its availability. Above all, *economic utility* is a core element of organizational efficiency. It depends on several parameters, especially validity, selection rate, and base rate as well as the variance in the performance criteria (that means, selection utility grows with the size of subsequent achievement differences). Supplemented by different economic indicators, the expected benefit can be calculated. Such calculations frequently lead to high utility estimates for the application of personnel selection instruments. *Advisory efficiency* may be understood as usefulness of diagnostic procedures to support individual occupational and organizational choice. Due to the relatively small general relationship between interests and abilities, such benefit is usually assumed. Advisory efficiency is important primarily in job counseling at labor agencies, but also in the context of organizational personnel development.

5.3 Applicants' Reactions

The applicants' *acceptance* of the selection process and their reactions to personnel selection methods is considered an independent quality criterion. Procedures which are better accepted are distinguished by information about job requirements as well as by transparency, feedback, and the possibility to control the situation. These requirements are better fulfilled in interactive procedures (i.e., interview) than in paper-and-pencil-tests or in biographical documentation (i.e., school grades).

5.4 Ethical and Legal Aspects

Ethical, professional, as well as legal aspects of personnel selection have received increasing attention. Examples for concrete ethical problems are: use of undue diagnostic methods, negligence of job requirements, application of intended distress during selection procedures, unjust invasion of privacy, lack of confidentiality of personal data, conflict of interest in relation to the employers and the clients. In this context, endeavors have been intensified to organize selection processes as fair and socially acceptable procedures (Schuler et al. 1993).

The appropriate legal basis—in Germany it is the general individual law as well as the labor law—are subject to substantial international differences. In Europe, an adaptation process takes place at present.

6. Concluding Comments

The adequacy of the application of personnel selection instruments in specific cases depends on a number

of factors. If we disregard all required differentiations, the value of diagnostic information for the most relevant occupational groups can be judged as is presented in Fig. 4, which gives a summary of all is discussed above, that is, validity, efficiency, social validity (acceptability and fairness) as well as ethical and legal aspects. We have to get used to the idea that all these aspects will be important for the use of personnel selection methods in the future.

As a result of innovative instruments of personnel selection being vividly required by practitioners, the chance for the development and application of new approaches to assessment has increased. However, our insight into the incremental validity of additional methods or the value of combined procedures has not improved in the same way. Once science has moved towards that direction, we could approach a project that at this point of time still has the character of a vision—to draw diagnostic information not only from single, specifically constructed procedures, but from a variety of human characteristics. Performance results may be combined with self-appraisals and other assessments, evidence on abilities may be drawn from preferences and personal values, and biographical incidents, in connection with physiological data and even characteristics of the physique or other tabooed indicators, may have their place in highly valid predictor combinations.

However, one prerequisite for such a multi-indicator diagnosis are models that go beyond the available multivariate statistics, although current structural equation models may represent one step into that direction. One possible attempt is to apply the principles of fuzzy logic to validity estimation of such combined conclusions. On the other hand, the perspective of the employee or, as we call it, the *social validity* of these procedures must not be overlooked by

Pes

Pestalozzi, Johann Heinrich (1746–1827)

1. Introduction

Johann Heinrich Pestalozzi was one of the most distinctive writers of his time, and was already regarded as one of the most famous pedagogs in Europe in his own lifetime. He owed his reputation as a writer essentially to his best-selling novel *Lienhard and Gertrud* (1781), and owed his fame as a pedagog to his work in Stans (1799), Burgdorf (1800–1803) and in Yverdon (1804–1825) where for 21 years he directed an institute in which children from all over Europe were educated.

Johann Heinrich Pestalozzi's work deals with a wealth of subjects in the fields of general politics, social policy, constitutional law, jurisprudence, literature, anthropology, philosophy, pedagogy, and social pedagogy, and it is documented in 30 volumes in the Critical Edition *Sämtliche Werke und Briefe*, 15 of which have hitherto appeared (also available on CD-ROM).

Pestalozzi was, in both his personal and literary life, actively opposed to social injustice, oppression, exploitation, dependence, and lack of political freedom. His ambition was to free the poor and their children from powerlessness, to help them to be able to secure their own individual subsistence, as well as to abolish the very political conditions which caused this hardship. He constantly gave central importance in his work to social justice, the satisfaction of needs, ownership and work, domestic order, and basic needs for all, including children. The subjects he addressed were rooted in social reality. Pestalozzi reflected upon and analyzed the everyday life of the poor masses, the everyday life of children, and the everyday political life of his time.

The special form of this relation to reality Michel Soetard (1981) has convincingly called the 'Principle Reality.'

2. Life and Work

2.1 1746–1799: Childhood, Youth, and Early Career

2.1.1 Family origins and childhood. Johann Heinrich Pestalozzi was born in Zurich on the 12

January 1746, the son of the surgeon Johann Baptist Pestalozzi and his wife Susanna, née Hotz. At that time, Zurich was a center of European culture, a city state with an exclusive merchant and entrepreneurial aristocracy. The town was regarded as rich, with a small number of old families holding power in the city council. Neither his father's family nor his mother's—who originally came from the Zurich area where her father was a parish priest—belonged to this group. The married couple produced seven children in 9 years of marriage from which only three grew to maturity. When Pestalozzi—one of seven children—was 5 years old, his father died at the age of 33, leaving his mother to take care of four small children. In order to lead a bourgeois life in spite of the financial predicament, economizing and making-do became a staple of their dismal everyday life. Pestalozzi had therefore to endure poverty. In the country at his grandfather's house in Höngg, where his grandfather was a parish priest, he became acquainted early on with the miserable social condition of the provincial population which was to occupy him for a lifetime.

2.1.2 School and studies. In Zurich, Pestalozzi—who had the civic rights—grew up with the sons of the patrician families whose carefree material situation was permanently laid out before his eyes. He enjoyed the schooling of a city-dweller, and went to the city elementary school from 1751 to 1754; he was then a pupil from 1754 to 1763 at the Schola Abbatissana in Zurich, the Schola Carolina, and the Collegium humanitatis (also in Zurich), the latter being a Latin school. After some initial difficulties he was a good pupil, though because of his financial situation he was always an outsider because of his 'extraordinary carelessness and uncleanness.' From 1763 to 1765 he studied at Zurich's theological college, the Carolinum. The appearance of an anonymous pamphlet he had co-written caused the abrupt end to his studies. It was clear to him in any case that he did not wish to become a priest.

In Zurich there were—following the example of other European countries—patriotic and physiocratic societies. From 1764, Pestalozzi belonged to the circle of patriots of the Helvetic Society. The Zurich scholars Bodmer and Breitinger in particular had their circle of influence here. The much-admired model was Rousseau. Republican works were read and written. It

was in this context that Pestalozzi's first publications *Agis* (1766) and *Wünsche* (1766) appeared. In 1767, Pestalozzi began a short agricultural apprenticeship with the Bern physiocrat Tschiffeli.

2.1.3 Livelihood. In February 1769, Pestalozzi became a farmer in Müllingen and ran into heavy debt. On 30 September 1769, he married *Anna Schulthess* (1738–1815), and on the 13 August 1770 their only child Hans Jakob, called Jaqueli (1770–1801), was born. Pestalozzi built a manor house, the 'Neuhof auf dem Birrfeld' which he moved into with his young family in 1771. Crop failure, bad purchases of land, and other mistakes led to failure and almost to financial ruin. In 1794, he founded an institution for the poor at the Neuhof. His initial interest was more entrepreneurial than pedagogical; in his *Neuhof-Schriften* (published in 1777), Pestalozzi accompanied his essays with a journalistic advertising campaign for support for his project. In his *Bitte an Menschenfreunde*, he successfully enlisted the support of, amongst others, Niklaus Emanuel Tschärner (1727–1794), the chairman of the Bern Society for Economics. Pestalozzi discovered his interest in all things pedagogical during his time at the Neuhof, motivated by his interaction with the poor children of the Neuhof: 'I saw how the overwhelming cruelty of self-interest constantly destroys the body and soul of almost—and I mean almost—all of these children.' Pestalozzi's institution failed financially, but he was later to make use of his experiences in the field of national education.

In the middle of the Neuhof crisis, the political work about Zurich *Freyheit meiner Vaterstadt* (1799)—which remained unpublished—was written in which he lamented the wealth of the city and its devastating effects on the constitution and political culture of Zurich.

2.2 From 1780 to 1799: Livelihood as an Independent Writer

Out of the necessity of having to finance himself, Pestalozzi became a writer. In 1780 he published *Abendstunde eines Einsiedlers* whose theme is cultivating people: 'Cultivating people towards the truth means cultivating their being and their nature towards a reassuring wisdom.' Then he wrote the first part of *Lienhard und Gertrud*, which appeared in 1781. *Lienhard und Gertrud* is a pedagogical novel which its author broadened into a novelistic pedagogical text. The theme of the novel is the story of the education and cultivation of an entire village. With *Lienhard und Gertrud*, Pestalozzi wrote about a fictitious village which he called Bonnal in a novel showing both the development and the education of the characters. The subject of the novel is bound together by a kal-

eidoscope of multifaceted and fictitious stories of education, cultivation, and socialization.

In the second (1783) and third (1785) books, it becomes clear how many individual fates have been embroiled in the deplorable state of affairs in Bonnal for many years, and that it is thereby not only a question of individual error, but at the same time of failings which lie more deeply in the political structure. Only in the fourth book (1787) does it become possible to continue telling the story of Bonnal and to organize it structurally as a story of reform, with, of course, further novelistic twists and turns and subplots. The village as the scene of the action is increasingly abandoned. Paragraph by paragraph Pestalozzi outlines his ideas for new legislation, the distribution of land, jurisdiction, and the culture of debate and justice. The novel is therefore increasingly interrupted on the level of action and plot, becomes more difficult to read, and thus loses its original novelistic character. The literary code transforms into a politically discursive text. *Lienhard und Gertrud* became Pestalozzi's greatest literary success. Pestalozzi was soon to become known far beyond the Swiss borders, first of all not as a pedagogue, but as a writer. The novel brought him the title of Honorary Citizen during the French Revolution.

In *Gesetzgebung und Kindermord* (written in 1780 and printed in 1783), Pestalozzi declared the prevailing legal practice throughout Europe of executing child-murderesses—mostly after extreme humiliation and torture—as inhuman. He mounted an emotive defence of a large number of child-murderesses, whom he viewed as innocent. To him, poor girls and women had the fundamental right to sexuality and marriage, to their children, to protection and support, and to recognition and help. The work was a plea against capital punishment.

In 1782, Pestalozzi published *Christoph und Else*, a novel of instruction, even a 'novel' for the novel *Lienhard und Gertrud*. It was to be used as a guide to how adults should read *Lienhard und Gertrud*. A peasant family talk together over 30 evenings about the plot, the theme, and the constellation of characters in *Lienhard und Gertrud*. On 26 August 1792, Pestalozzi was appointed an Honorary French Citizen and never renounced the honorary title in spite of all the criticism of the Terror, an action which aroused suspicion in conservative circles. The outcome of Pestalozzi's examination of the revolution was the work *Ja oder Nein?* (1793) in which he made the Ancien Régime responsible for the devastating outrages in Europe and thus justified the revolution, though at the same time he sharply denounced the revolutionary Terror.

In 1797, Pestalozzi's main philosophical work *Meine Nachforschungen über den Gang der Natur in der Entwicklung des Menschengeschlechts* appeared. The initial question was 'What am I, and what is mankind?' Pestalozzi expounded a natural state, a social state,

and a moral state of humanity, and went on to discuss the individual human being as a ‘work of himself,’ a ‘work of nature,’ and a ‘work of morality.’

In 1798, the revolution also reached Switzerland. For a short time, a Helvetic Republic was established. Pestalozzi became the editor of the ‘*Helvetisches Volksblatt*’—the publication organ of the new Helvetic government—and at first worked on behalf of the government. He wrote texts, appeals, and pamphlets, as well as *Abhandlung über die Natur des Helvetischen Zehnden*. Whereas the typical pamphlets on both sides at the time of the revolution constituted obvious works of political agitation in favor of one side or the other, Pestalozzi was a mediator who urged the often very hostile opposing groups towards agreement. He became a soother of passions in his pamphlets. Pestalozzi wanted to promote the unity of the Swiss in the crisis year of 1798, the unity between the poor and rich population, the unity of town and country, and the unity of the Inner-Swiss (Catholic) cantons and the majority Protestant cantons.

2.3 1799–1827 The Pedagog and Institute Director: From Stans to Yverdon

2.3.1 Stans. At the age of 53, Pestalozzi received a government commission to run an orphanage in Stans. From 7 December 1798 to 8 June 1799, he lived there together with a housekeeper and as many as 80 children by the end. His pedagogical work and his pedagogical writing were now supported by two pillars. The first was a love of children and a passion for his work. Pestalozzi made himself into the ‘father’ and ‘mother’ of all the children; he tried to transpose the notion of the great importance of satisfying basic needs. The second was that the fundamental principle of the ‘method’—which was on the one hand an almost technocratic syllabic reading method—was at the same time elevated by the idea of an elementary method of moral education. From then on, Pestalozzi’s elementary education and elementary method were central themes. The institute, however, came to a sudden end. Pestalozzi had to hand over the building to French soldiers returning from the Russian campaign for use as a hospital and leave the institute, an action which made him fall into deep depression and despair. During this time, he wrote his strongly influential work, the *Stanser Brief* (1799), which contained a passionate plea for the malleability of human beings, including, and indeed especially, for the malleability of poor, neglected children.

2.3.2 Burgdorf. Pestalozzi became a teacher in Burgdorf on 23 July 1799. The announcement of a

schoolmasters’ conference in Burgdorf Palace followed on the 24 October 1800. The appearance of *Wie Gertrud ihre Kinder lehrt* followed in 1801. In the first part, Pestalozzi reported on Stans in autobiographical form, on his first endeavors in Burgdorf, on his young colleagues, some of whom accompanied him for a considerably long time, and on how he conceived method, the unity of knowledge, ability, and feeling. Pestalozzi developed a research program which he continued in Yverdon and which aimed at developing suitable learning aids in the three directions which he soon named ‘HeadHeartHand.’ The principles of the new teaching method consisted of the ability to visualize, simplification, logical progression, and individualization. The method was aimed at developing the autonomy of the child, at creating an independent personality which could secure its own subsistence. From November 1802 to February 1803, Pestalozzi traveled to Paris as a member of the Consulta. He was, however, unable to push through his concept for national education there. In June 1804, the institute at Burgdorf was moved to Müncbuchsee, and at the end of August the opening of a subsidiary institute followed in Yverdon, a town in French-speaking Switzerland, and on the 6 July 1805, Müncbuchsee was closed.

From 1804 to 1825, Pestalozzi ran one of the largest European educational institutes of the time in the rooms of the palace at Yverdon in French Switzerland. Yverdon was an experimental school on the level of its teaching, education, and teacher training. In order to be able to disseminate the new knowledge acquired from the everyday pedagogical research, a printing works was set up specifically for this purpose. Pestalozzi, who until that time had always written his works alone, now published journals, teaching books, teaching material, discourses on teaching methods, appeals, and speeches with his colleagues. At the center of these works stood Pestalozzi’s concept of an elementary education of people which could be applied to different teaching disciplines.

At the height of its impact in 1809, the institute had 150 pupils from 6 to 16 years old, 31 teachers and assistant teachers, and 40 young people as observers from all over Europe who wished to study Pestalozzi’s method. Pestalozzi’s concept of elementary teaching was already being followed ever more closely in Prussia, Spain, and many other countries. Pestalozzi’s most important work from the Yverdon period is *An die Unschuld, den Ernst und den Edelmut meines Zeitalters und meines Vaterlands* (1815), a treatise in the form of an address in which Pestalozzi set out his program for life: ‘The beginning and the end of my policy is education.’ Pestalozzi analyzed the approach of the industrial age with its phenomena of concentration, mechanization, and standardization. Only in education did he see the means to prepare people for the Industrial Age. The work caused a great sensation and was a literary success.

The size of the staff and the differences of interest and opinion within the teaching body increasingly led to endless quarrels which finally caused the downfall of the institute. Pestalozzi left Yverdon embittered in 1825, and returned to the Neuhof.

In the last 2 years of his life, he wrote the works *Meine Lebensschicksale als Vorsteher meiner Erziehungsinstitute in Burgdorf und Iferten* (1826), the *Schwanengesang* (1826), and finally the *Langenthaler Rede*. During the crisis which industrialization and the reorganization of the states into large administrative states gave rise to, Pestalozzi saw a great opportunity for man to return to himself, and for his inner renewal by means of a comprehensive elementary education.

After a short illness, Pestalozzi died on 17 February 1827. On 19 February, he was buried near the Neuhof in the small village of Birr.

3. Critical Reception and Research Developments

The research literature on Johann Heinrich Pestalozzi's life and work, amply documented by the research papers and synopses of the Pestalozzi literature of the past 200 years, at first glance appears immensely extensive. This lies in the fact that Pestalozzi, in the history of (German-speaking) pedagogy and educational sciences, has without doubt experienced a considerable *impact* history which has admittedly only to a certain degree coincided with the *reception* history of his numerous written works. Above all, Pestalozzi's teaching method is prescribed in many countries around the world and his best-known works have been translated into many languages. Should one follow the numerous publications up to the present, it becomes apparent that, whereas in the first half of the twentieth century the 'whole Pestalozzi' became the subject, individual or partial aspects began, however, to dominate more and more markedly within the framework of the differentiation of educational science and its adjacent sciences. In this way, the paradigm exchanges in educational science are mirrored in the respective cognition interests of analyses. If the Pestalozzi from the history of ideas took center stage in scientific literature in the middle of the twentieth century, the research controversy about the *political Pestalozzi* (Rang 1967) was sparked off in the 1960s and 1970s. In the course of the 1970s with its far-reaching education and school reform, interest was then concentrated rather more on the practitioner and reformer. Within the research history, it furthermore became clear that, after a very intensive, bibliographically broad and verifiable acceptance of Pestalozzi the politically reforming pedagog, the research in the 1980s stagnated; indeed the number of papers and studies about Pestalozzi fell off considerably. That only changed in 1996. Since then, the trend has been moving in the direction of an examination of the research into context and reception (the impact history) alongside biographical research using new

scientific methods, aimed at producing a differentiated situating of the work as regards history and content. An important impetus comes from the work of the Pestalozzi Research Center which, dividing the work between the Pestalozzianum and the University of Zurich, is pushing forward with the Critical Edition, and publishes the *Neue Pestalozzi-Studien* and the *Neue Pestalozzi-Blätter*.

Pestalozzi's journalistic work is so diverse that it not only touches on areas of social and cultural practice as regards content, or even focuses on them explicitly as a central theme, but also represents groups of different discourse methods. In order to understand the work, interdisciplinary research is required e.g., into rhetoric, eloquence and discourse, the socioaesthetic culture of sentimentalism, social history, the relationship between the written and the spoken, the problematic nature of text selection, the relationship between truth and fiction, the theory of femininity and the ensuing mother cult of the eighteenth century.

Phantom Limbs

Many patients awake from the anesthetic after an amputation feeling certain that the operation has not been performed. They feel the lost limb so vividly that only when they reach out to touch it, or peer under the bedsheets to see it, do they realize it has been cut off. This startling realization does nothing to subdue the reality of the limb they experience, and may even intensify the sensations that define it. The first detailed description of this phenomenon was provided by the American Civil War surgeon, Silas Weir Mitchell (1871), who dubbed it the 'phantom limb.' The term so accurately captures the nature and subjective experience of the phenomenon that it has been adopted ever since. This entry reviews the nature of phantom limb pain and nonpainful phantom limb sensations which arise after limb amputation.

1. Phantom Limb Pain

For many amputees, a distressing problem is phantom limb pain. While the distinction between a painful and nonpainful phantom is not always clear-cut, it is useful to separate them for purposes of description, classification, and treatment. Painful phantom experiences vary in a number of dimensions. These include intensity, quality, location, frequency, and duration. Many amputees report a painful intensification of the tingling, 'pins and needles' or *paresthetic* quality (i.e., dysesthesias) that defines the nonpainful phantom limb. Some sufferers describe bouts of paroxysmal shooting pain that travel up and down the limb. Others report the phantom to be in a cramped or otherwise unnatural posture that gives rise to excruciating pain. Many amputees describe the pain in the phantom limb as indistinguishable from the pain they experienced in the limb before amputation. In still others, the phantom may be immobile or paralyzed so that attempts to move it generate pain. Finally, the phantom is often the seat of an intense burning pain, as if the hand or foot were held too close to an open flame. Frequently amputees suffer from several types of pain. Phantom limb pain, it appears, is equally prevalent among men and women, and is not related to side, level, age, or cause of amputation (Jensen and Nikolajsen 1999).

Surveys based on several thousand amputees reveal that between 78 percent and 85 percent of patients continue to experience significant amounts of phantom limb pain more than 25 years after amputation (Sherman et al. 1997). Prospective studies of the

incidence of phantom limb pain are consistent with these estimates (Jensen et al. 1985, Nikolajsen et al. 1997). Between 50 percent and 71 percent of amputees report phantom limb pain two years after amputation. There is a reduction in the frequency and duration of attacks over time. Equally striking is the low success rate of treatments for phantom limb pain: in the long term only 7 percent of patients are helped by the more than 50 types of therapy used to treat phantom limb pain (Sherman et al. 1997).

The different qualities of phantom limb pain, its high prevalence and incidence, and its low treatment success rate point to the complexity of the problem. Phantom limb pain is not a unitary syndrome, but a symptom class, with each class subserved by different etiologic mechanisms. There is not just one cause of phantom limb pain. The development and severity of this disorder are determined by the interaction of multiple factors that vary across individuals. These include ectopic activity from peripheral nerves that were transected during amputation and have formed a neuroma, contributions from the sympathetic nervous system, sensitization of central nervous system structures due to the effects of amputation, inflammation and ectopic activity, alterations in the functional organization of sensory nuclei, past experience with pain, and the immediate physiological, motivational, and psychological states of the individual.

1.1 Pain Memories in Phantom Limbs

A striking property of phantom limb pain is the presence of a pain that existed in a limb prior to its amputation (Katz and Melzack 1990). This class of phantom limb pain is characterized by the persistence or recurrence of a previous pain, has the same qualities of sensation, and is experienced in the same region of the limb as the pre-amputation pain. Cases studies of amputees have revealed pain 'memories' of painful diabetic foot ulcers, bedsores, gangrene, corns, blisters, ingrown toenails, cuts and deep tissue injuries, and damage to joints and bony structures. In addition, the phantom limb may assume the same painful posture as that of the real limb prior to amputation, especially if the arm or leg has been immobilized for a prolonged period.

The proportion of amputees who report similar pain before and after amputation may be as high as 79 percent (Katz and Melzack 1990), although according to prospective studies, the incidence is approximately 10 percent at one year after amputation (Jensen et al. 1985, Nikolajsen et al. 1997). Pain also persists in patients with deafferentation that does not involve amputation. In these conditions, the involved body part is still present but it is devoid of sensibility due to an interruption in the supply of sensory (afferent) information (i.e., deafferentation). Brachial plexus avulsions, in which the sensory nerve roots supplying the arm and hand are torn from the spinal cord, often

produce pain that is felt in the deafferented and anesthetic region. Similarly, patients with spinal cord injuries may complain of pain referred to body parts below the level of the transection, including, for example, a patient who continued to feel the pain of an ingrown toenail after a complete spinal cord break.

Painful and nonpainful sensations also persist or recur after surgical removal or deafferentation of body structures other than the limbs, such as breasts, teeth, and internal and special sense organs. Ulcer pain has been reported to persist after subtotal gastrectomy with removal of the ulcer. Patients have reported labor pain and menstrual cramps after total hysterectomy, rectal pain and hemorrhoids after removal of the rectum and anus, the burning pain of cystitis after complete removal of the bladder, and the pain of a severely ulcerated cornea after enucleation of an eye.

As noted above, not all phantom limb memories are of painful experiences. Nonpainful preamputation sensations do recur, but they are not as common and tend to include the sensation of objects that were once worn on the limb. These *superadded* sensations vary in complexity from such simple somatosensory qualities as the sensation of bandages that once wrapped a wound, a plaster cast, finger rings, and wristwatches to the multimodal, perceptually integrated phenomenon of a phantom foot clad in a sock and a shoe of specific type and color (Katz and Melzack 1990).

Taken together, these case reports and studies of amputees reveal that pain memories are not merely images or cognitive recollections; they are direct experiences of pain that resemble an earlier pain in location and quality. They are perceptually complex experiences that may even involve information from multiple sensory modalities including visual, olfactory, tactile, and motor components that had accompanied the original experience. The precise details of the experiences of pain involve localization, discrimination, affect, and evaluation—that is, all the dimensions of perceptual experience—and these properties are a function of integrated brain activity. It is likely that the outputs of sensitized spinal cells activate the neural structures in the brain that subserve memories of earlier events.

2. The Nonpainful Phantom Limb

The most salient property of the nonpainful phantom is the tingling, paresthetic quality, but sensations of temperature, posture, length, volume, and movement are also very common (Jensen and Nikolajsen 1999). The incidence of the nonpainful phantom is estimated to be between 80 percent and 100 percent. In fact, the presence of a nonpainful phantom is so common that it is considered a 'normal' sequela of amputation. It is standard practice to prepare the patient preoperatively for its subsequent occurrence.

The frequency with which a painless phantom occurs does not appear to be related to the extremity,

Figure 1

Illustrations of a patient who sustained a complete forequarter amputation of his right shoulder in a work accident and later developed phantom limb pain. The figurines depict the process of telescoping following a series of treatments with transcutaneous electrical nerve stimulation. Dots represent points where stimulation was applied. Arrows indicate the sites of referred phantom limb sensations

Source: Adapted from Katz and Melzack 1987, with permission

A The patient reported a phantom limb of normal length that consisted of only the lower arm and hand, with a gap between the shoulder stump and phantom elbow. During stimulation applied at a point above the clavicle, the patient reported that his phantom hand began to swell and become warm.

B In response to stimulation applied at a point on his right ear, he remarked that his phantom arm had 'telescoped' into the stump so that the elbow protruded from the stump.

C Later, stimulation of the same point resulted in a further retraction of the phantom, leaving only the wrist and hand attached to the stump

side, level of amputation, age, gender, or reason for amputation (Jensen and Nikolajsen 1999). There is considerably more variability in the estimates of the duration of the nonpainful phantom. In some amputees, the phantom may disappear within days or weeks of the amputation. In others, it remains unchanged for up to 60 years.

2.1 Fading, Telescoping, and Shrinking of the Phantom Limb

In many cases, the normal phantom undergoes a number of predictable changes within several years of amputation (Katz 2000). These include fading, telescoping, and shrinking. Immediately after amputation the phantom limb usually feels of normal length and size. Over time, the proximal portions begin to fade and soon disappear (Fig. 1). At this point, the phantom limb consists of only the extremity and major joints. These are felt at a normal distance from the body. The intervening parts have disappeared so that the phan-

tom hand or foot feels as if it were hanging, unattached, in empty space. In the case of an amputation performed at the shoulder, the phantom limb may consist of only the lower arm and hand, with a gap between the shoulder stump and the phantom elbow. In approximately one-third of amputees, a process of 'telescoping' begins. Among upper extremity amputees, the phantom is perceived gradually to approach the stump so that the hand is located in phenomenal space on a level with the elbow of the other arm. As the process continues, the gap between the stump and phantom continues to close; the amputee may find that the hand is protruding from, or attached to, the end of the stump. Later, the phantom hand may retract into the stump so that only the tips of the fingers jut out. In some cases, eventually even these may disappear completely and permanently into the stump.

There are times when a completely telescoped phantom will temporarily lengthen so that the hand or foot is once again felt at a normal distance from the stump. Less commonly, the converse also occurs; a phantom which is already telescoped may temporarily retract completely into the stump, or one which is of normal, or shortened length may become even shorter. The circumstances and stimuli which bring about these changes are extremely varied and range from peripheral stimulation of the stump and other regions of the body to more central influences.

The process of telescoping is sometimes accompanied by a marked shrinking of the phantom to the dimensions of a child's limb. This gradual diminution in perceived size or volume occurs in both upper- and lower-limb amputees. The extent of shrinking that occurs is variable. Adult amputees have reported the phantom to be the size of a doll's or baby's hand, a silver dollar, or even as small as a postage stamp (Katz 2000).

2.2 Cortical Maps and Phantom Limbs

Factors governing the fading, telescoping, and shrinking of the phantom are not well understood. The gradual fading of the phantom is thought to represent a perceptual correlate of the re-establishment of inhibitory control over hyperactive or spontaneously active cells which subserve the phantom. The gradual telescoping and shrinking have been hypothesized to depend upon input from intact peripheral fibers located in the stump. These experiences appear to be perceptual markers of the short- and long-term re-organizational changes that occur after amputation in central nervous system structures including the somatosensory cortex (Katz 2000, Merzenich et al. 1984). The perceived distance between the phantom and the stump may be a function of the distance separating their respective representations in the cortical map.

2.3 Psychophysical Correlates of Phantom Limb Sensations

Although a normal phantom occurs whenever nerve impulses from the periphery are blocked or otherwise removed, it is also true that direct stimulation of the amputation stump frequently exaggerates the tingling or paresthetic quality of sensation typical of the painless phantom limb. Careful questioning of amputees reveals that the nonpainful phantom limb is not perceived as a static phenomenon. The paresthetic quality of sensation, which defines the phantom limb percept, is in a constant state of flux, with changes occurring in intensity, body part, or both.

One mechanism that accounts for the paresthetic component of the phantom limb is a cycle of sympathetic-efferent somatic-afferent activity (Katz 2000). Changes in the intensity of phantom limb paresthesias reflect the joint activity of cholinergic (sudomotor) and noradrenergic (vasomotor) postganglionic sympathetic fibers on primary afferents located in the stump and stump neuromas. Release of acetylcholine and norepinephrine from postganglionic sympathetic fibers produces transient vasoconstriction and heightened skin conductance responses. In addition, neurotransmitter release onto apposing peripheral fibers trapped in stump neuromas increases primary afferent discharge. This information is transmitted rostrally, where it gives rise to referred phantom sensations upon reaching central structures subserving the amputated parts of the limb. The moment-to-moment fluctuations in the intensity of phantom limb paresthesias reported by many amputees may, in part, reflect a cycle of sympathetic-efferent somatic-afferent activity. Increases in the intensity of phantom limb paresthesias would follow bursts of sympathetic activity, and decreases would correspond to periods of relative sympathetic inactivity. If central sensitization has also developed, through prior injury, trauma during amputation, or peripheral inflammation, or if the sympathetic-sensory coupling involves nociceptors, the sensation may be one of dysesthesia.

2.4 Psychological and Emotional Processes Influence the Phantom Limb

The idea that emotional and psychological processes can cause pain traditionally has been tied to the notion of psychopathology. However, it is becoming increasingly clear that under certain circumstances pain may be triggered by these processes in psychologically healthy individuals as well. The aggravation or alleviation of pain referred to phantom body parts may be mediated in part by psychological processes that alter anxiety levels. Phantom breast pain after mastectomy is provoked by emotional distress in 6 percent of women three weeks after surgery, and in 29 percent one year later. Of lower-extremity amputees, 50 percent report that attacks of phantom limb pain are

Figure 2
